SINCE the first issue, just ten years ago, of the admirable treatise by Messrs. Batson and Hyde on the testing of constructional materials, notable developments have taken place, particularly in regard to the standardisation of methods of testing. The British Standards Institution has issued a number of important specifications, and advantage has been taken of the opportunity afforded by a second edition of the book to incorporate in full measure the Institution's requirements. The chapters on fatigue testing, hardness testing, and testing at high temperatures have been enlarged in order to record the rapid progress made in these branches of work. These and other additions and emendations enhance the value of a work which has already gained a well-merited degree of popularity among students and experts alike. B. C.

Co-operation in Danish Agriculture. By Harald Faber. An English adaptation of " Andelsbevægelsen i Danmark " by H. Hertel. New edition. Pp. xxii + 188. (London, New York and Toronto: Longmans, Green and Co., Ltd., 1931.) 9*s.* net.

IT is not surprising that the first edition of Mr. Faber's excellent book is exhausted and that a second edition should be called for. In this he has embodied the results collected by Mr. Hertel and published in 1929, so that he has been able to bring his information up to date; he has also incorporated material from recent official statistical publications in Denmark. The book appears at an opportune moment, when the agricultural policy of Great Britain is being seriously reconsidered, and when the co-operative methods which have done so much for Denmark are being studied with the view of seeing if they would not prove equally helpful here, at any rate with appropriate modifications. Mr. Faber's account is authoritative, lucid, and impartial; the book can be commended to all students of agricultural problems.

Le problème de l'évolution. Par Prof. Maurice Caullery. (Bibliothèque scientifique.) Pp. 448. (Paris: Payot et Cie, 1931.) 40 francs.

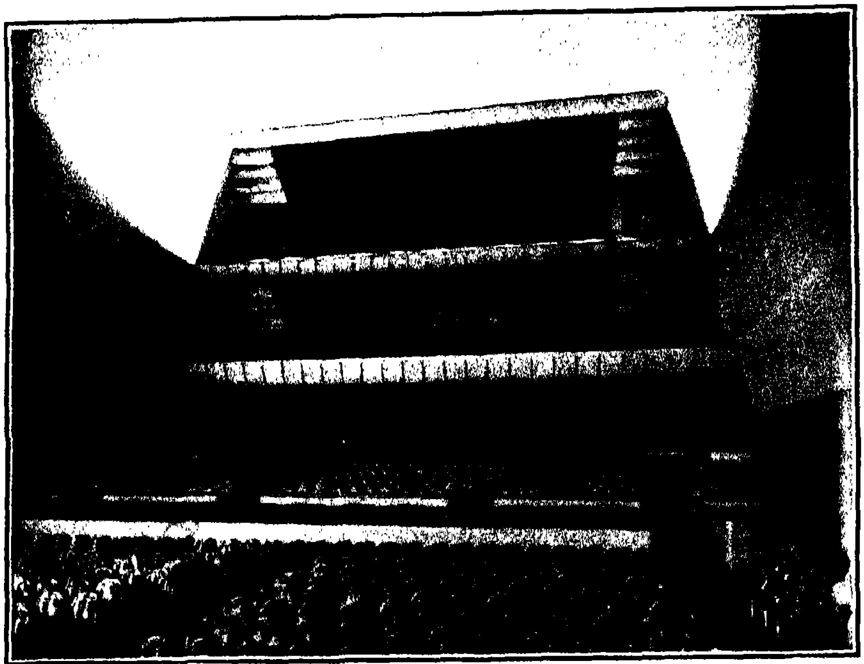
IN this excellent work, the author covers, in just over four hundred pages, all the fundamental landmarks and theories of the epic of evolution. The first part of the book is mainly devoted to a discussion of the palæontological discoveries supporting evolution, while the second part explains and criticises the various theories put forward to explain evolution. The author is not entirely satisfied with mechanism, and mentions the doctrine of emergence as offering a suggestive ground for reconciling facts and theories. Yet he does not find it wise, at the present state of our knowledge, to venture into dogmatic assertions about the final value of evolution. T. G.

Conditions and Consequences of Human Variability. By Prof. Raymond Dodge. Published on the Louis Stern Memorial Fund. Pp. xi + 162. (New Haven, Conn.: Yale University Press; London: Oxford University Press, 1931.) 11*s.* 6*d.* net.

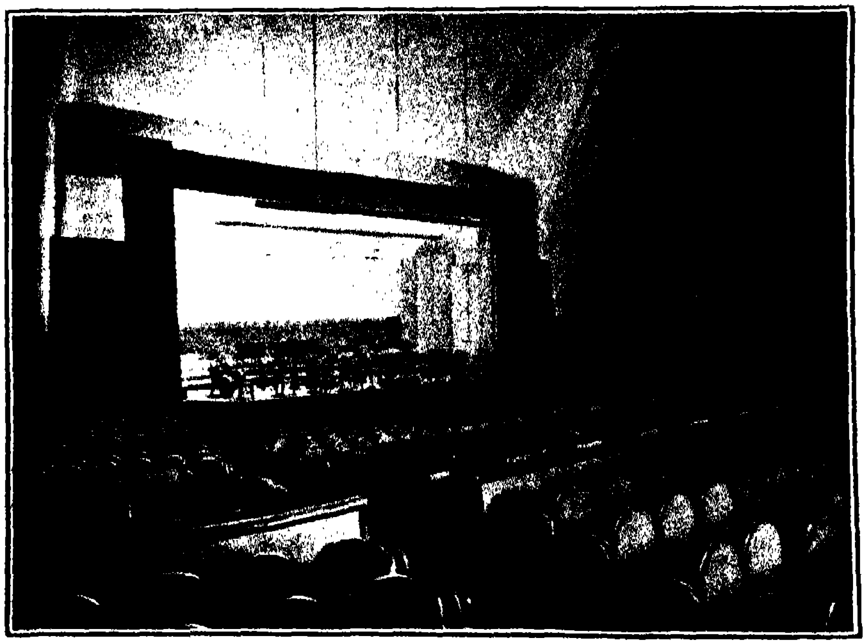
PROF. DODGE has discussed the significance of variability of mental development. The author groups himself amongst the supporters of the *Gestalt* movement: he calls himself a " behaviouristic Gestalt ". He is not satisfied with psycho-physical parallelism, and puts forward his hypothesis of apperceptive integration, that is, an integration which would approximately result in consciousness and which takes place in the brain.

The Salle Pleyel, Paris, and Architectural Acoustics

THE meetings of the Second International Congress of Electricity, recently held in Paris, took place in the great building newly constructed by the Pleyel Company in the faubourg Saint Honoré, and there are probably few among those present who were not impressed by the faultless acoustics both of the Great Hall, where the inaugural and other meetings were held, and of the so-called *Salle Chopin*, where the meetings of Section 1, devoted to pure physics, occurred. The Great Hall can accommodate some three thousand auditors, and yet, as the present writer proved, a speaker reading from a paper in the ordinary tone of a lecturer in a small class-room can be heard perfectly in various parts of the hall, including the back of the upper gallery, more than fifty yards away. The principles upon which this hall was designed by M. Gustave Lyon are very simple, but there is no doubt as to their efficacy in this and other examples of his work.



Photo] FIG. 1.—Auditorium of the Salle Pleyel, seen from the stage. [Chevojon.



Photo] FIG. 2.—Stage of the Salle Pleyel, seen from about the middle of the parterre. [Chevojon.

The reflections which take place at the walls of a hall are absolutely necessary for good hearing, since without reinforcement of this kind a normal speaking voice is inaudible at a very short distance. A curious experiment was carried out by M. Lyon on this point at Challais-Meudon. Two observers were suspended by cords below small balloons, which could be manœuvred to any desired distance apart, and it was found that, under such conditions, the speaking voice was quite inaudible at a distance of 11 metres. Similar results have been obtained on plains covered with soft new-fallen snow, which is a very bad reflector of sound, while, on the other hand, on perfectly smooth water at night a normal voice can be heard at a distance of more than a mile. Reflections are, then, indispensable.

On the other hand, if the interval between the reception of the direct and of the reflected sound is too large, an unpleasant effect is produced which with increasing interval soon resolves itself into

two distinct sounds. Estimates of the maximum permissible interval naturally vary somewhat. According to Ernst Petzold, it should not exceed $\frac{1}{20}$ sec. M. Lyon has carried out extensive experiments with trained musicians as his collaborators, and finds that a slightly longer interval may be

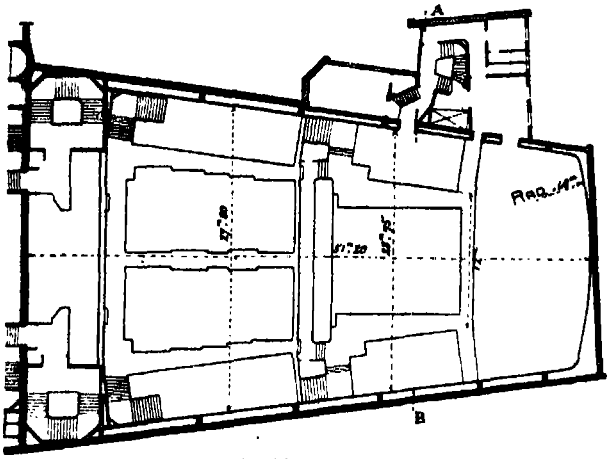


FIG. 3.—Plan of the hall.

allowed in practice. The least permissible interval is greater with such sounds as those of an orchestra than with staccato sounds, such as the noise of castanets or of an actor dying in the prescribed mode, and appears to run up to $\frac{1}{10}$ sec. for the former, but not to exceed $\frac{1}{15}$ sec. for the latter. In any event, $\frac{1}{15}$ sec., or, expressed as sound path, 23 metres, may be taken as a practical limit to which to work. This at once restricts the depth of the stage to 11 metres, if good reflection from the back wall is taking place, and, for the sake of listeners to one side, the breadth to 23 metres, if the whole stage is to be occupied by, for example, an orchestra. The stage in the *Salle Pleyel* is actually about 20 metres wide by 10 metres deep.

A hall is bounded by floor, ceiling, wall at back of stage (which we will call stage wall), side walls, and wall opposite stage (which we will call back wall). Any hall for a large audience will be much more than 11 metres long, which means that any echo from the back will make, for people near the stage, more than the permissible interval with the direct sound. Such echoes should therefore be completely suppressed. In the *Salle Pleyel*, this is effected by treatment with a special sound-absorbing material applied to curved surfaces, the general arrangement of which is clear, without lengthy description, from Fig. 1. The floor, with its padded seats, is a very bad reflector, and in any event waves reflected from it will strike the back wall and be absorbed. The side walls, as can be seen from Fig. 3, are thrown back so as to make an acute angle at the stage end. This allows a larger capacity than if they were parallel, and also ensures, as can be seen, that no reflection from the side walls can, with respect to the direct sound, lead to an interval exceeding the allowable limit. There remain the stage wall and ceiling, which are treated as essential reflectors, in the following manner.

The stage wall, AB in Fig. 4, has its vertical profile in the form of a circle, inclined so as to throw the sound over the whole parterre, and is 7 metres high. The distance SA is about 10 metres, so that, with this height, the interval between direct and reflected wave does not exceed $\frac{1}{15}$ sec. If AB were much higher, this condition would not be satisfied. The horizontal profile is likewise approximately circular, as shown in Fig. 3. The first part of what may be called the ceiling is the reflector BC, designed to throw the sound into the first gallery. The vertical distance between B and C is likewise 7 metres, and the interval condition is satisfied, as it is by the third reflector CD which completes the covering of the hall, and throws the sound into the second gallery. The harmonious appearance of the curves is shown by Fig. 2, which is a view of the stage from the middle of the hall, behind the row of boxes. The excellence of the hearing, even from the back of the second gallery, has already been mentioned.

The Pleyel building contains, besides the two smaller halls, of excellent acoustics, many other features of interest to the physicist no less than to the musician. There are a large number of absolutely sound-proof studios, each of which is a room of light construction; the whole weight of this room rests on a layer of sound-proof material, spread on the floor of a slightly larger enclosing room which forms part of the main structure. No conductor of sound, such as a nail or screw, connects the interior room with the framework of the building. The interior room has its own separate windows, opposite those of the main building. Here again the effectiveness of the design is astonishing, the most muscular piano-playing in one studio being completely inaudible in the next.

M. Gustave Lyon's very simple principles have found, perhaps, their most striking exposition in

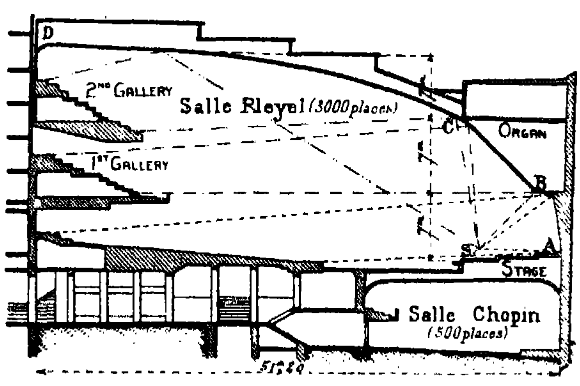

FIG. 4.—Vertical section of the hall.

the Great Hall, but he has behind him a series of remarkable achievements in the way of remedying, at small cost, the bad acoustics of certain halls, of which the best-known example is, perhaps, the hall of the Trocadéro at Paris, once notorious for its execrable sound properties, but now extremely satisfactory. His work is an excellent example of how far a little sound physics can be made to go in the hands of a man of bold originality and energy, who makes experiment and experience his guides.

E. N. DA C. ANDRADE.

Quantitative Estimates of Sensory Events

By Dr. ALLAN FERGUSON

An immense mass of literature has accumulated around the problem which was stated by Fechner more than eighty years ago as that of measuring the increase of a mental intensity in terms of the relative increase of the corresponding physical energy. His problem, in fact, was that of finding a quantitative measure of certain subjective sensations.

Other qualities apart, we can say of two sensation-brightnesses that they are *equal* in magnitude, that one is *greater* than the other, that one is *just perceptibly greater* than the other; the same may be said of two sensation-loudnesses. It is an unfortunate fact that such terms as loudness or brightness are used indiscriminately, sometimes in reference to the magnitude of the sensation, sometimes in reference to the magnitude of the stimulus which produces that sensation. It is desirable to adopt a uniform practice and, in what follows, these terms will be applied solely to the subjective sensations involved.

It seems, then, that just as in the region of physical stimuli we can use such terms as *greater*, *less*, and *equal*, so in the region of sensory events we can, and do, use the same terminology. Loudness and brightness are magnitudes, in the sense that colour and shape are not magnitudes. Are they quantitative magnitudes? Can we say by *how much* one loudness, or one brightness, is greater than another? This is a fundamental problem for psycho-physics, and it is essentially the question which Fechner essayed to answer.

Obviously the answer, logically treated, demands some knowledge of what we mean by measurement, and it is perhaps unfortunate for progress in psycho-physical work that the issue has, almost from the outset, been clouded by wranglings concerning the possibility of such measurements—arguments that have neither dealt adequately with the theory of measurement nor recognised the fact that quantitative physical magnitudes are not to be classed all under one head. Happily, the human mind is, in certain matters, reasonably illogical and, in the determination of purely physical magnitudes, physicists have been content to measure first and to theorise afterwards. Overmuch theorising concerning fundamentals is apt to have a paralysing effect: and it is well to be mindful of the fate of the centipede, who

> " . . . was happy quite,
> Until the frog, for fun,
> Asked her which leg went after which,
> Which raised her doubts to such pitch,
> She lay distracted in a ditch,
> Not knowing how to run ".

The psycho-physical measurements with which we are concerned have felt something of this paralysis; it is therefore a favourable augury for progress when we find Dr. R. A. Houstoun and Dr. L. F. Richardson, from different lines of approach, making quantitative measurements of sensation, without troubling overmuch to discuss their possibility.

It is perhaps simplest to approach the matter from the historical point of view. Gustav Theodor Fechner (1801–1887), physicist, poet, philosopher, and mystic, had unique qualities for the tasks which he faced—qualities, too, which were prone to raise suspicion in minds more prosaic than his own. This may account for some of the difficulties which his work encountered, as well as for the measure of success with which it met. It is essential, in order fully to appreciate those difficulties, to see Fechner against the background of his time and of his own philosophy, an animistic synthesis which should enable him " to follow consciousness itself into an underworld—a world which must then be no other than the abiding place of a general consciousness of which life is but a ripple on the surface ". Fechner, early in his endeavour to establish the relations which we have mentioned, chanced upon certain observations made by E. H. Weber about 1831. Weber had noted that, in a test on weight discrimination carried out according to certain specified rules, a skilled observer who could just discriminate between weights of 29 and 30 drams, could also just discriminate between weights of 29 and 30 ounces. Further, this relative sensitiveness remained the same over a fairly wide range. As it is usually stated, if, when the magnitude of the stimulus (*Reiss*) is R the just perceptible increase is δR, then, over a certain range,

$$\delta R/R = k.$$

The value of k in this particular instance is about 1/30.

With due precautions concerning experimental technique, and correct interpretation of the psychological conditions, the law holds for the sensory qualities associated with such diverse stimuli as sound, light, pressure, and even the stimulus to the sense of smell.

It must not be imagined that the law holds over more than a limited range. It obviously fails at the threshold of sensation and, if $\delta R/R$ be plotted as ordinate against R as abscissa, a curve results which is approximately horizontal over a very limited portion only—and it is to this portion that Weber's law applies.

Whether, however, $\delta R/R$ is constant, or is some complicated function of R, is a matter of little weight for the development of the rest of the argument. Let us, for the moment, confine ourselves to the region within which $\delta R/R$ is approximately constant. It is customary at this stage to point out (and the present writer confesses to what seems to be a lapse) that Weber's law, as thus stated, is quite unexceptionable, inasmuch as it is concerned exclusively with physical stimuli—weights which may be measured in dynes or in grams weight, sound intensities which may be measured in watts per square centimetre, and so on. This is, per-

haps, not quite correct, for, after all, δR is the *just perceptible* increase—the increase corresponding to an increase δS in sensation. What we have written as δR should therefore be written as a differential coefficient, and the statement of Weber's law should read

$$\delta R/\delta S = kR.$$

Stated in this form, the law may still be regarded as unexceptionable, though it is conceivable that some purist may criticise this form on the ground that it prejudges matters by assuming the existence of an *element* of sensation. However this may be, the next step, that of an integration of the equation just propounded, has been criticised on all hands. Integrated over the region for which Weber's law is valid, we find

$$S - S_0 = k \log (R/R_0),$$

where S_0 and R_0 refer to the values of S and R at an arbitrary origin within the prescribed region. Some curious algebraical exercises are to be found in the textbooks which give alternative methods of arriving at this relation, but it must be understood that *any* process by which one steps from the original statement of Weber's law to a statement of some functional relation between S and R involves an integration, implied or overt, and consequently involves the assumption that $\Sigma\delta S = S$.

And why not ? It would take too long here to discuss in detail the objections advanced, some of them apparently irrelevant, most of them variations on one theme.

Thus, William James remarks that when we consider sensations only, we are " quite unable to read any clear meaning into the notion that they are masses of units combined. To introspection, our feeling of pink is surely not a portion of our feeling of scarlet ; nor does the light of an electric arc seem to contain that of a tallow candle in itself. . . . Introspection shows, moreover, that in most sensations a new *kind* of feeling invariably accompanies our judgment of an increased impression ; and this is a fact which Fechner's formula disregards." Again, Stumpf says : " An sich ist und bleibt unlängbar, dass eine Empfindung nicht das Mehrfache einer anderen sein oder wenigstens nicht als solches erkannt werden kann. Mussten wir doch sonst die eine von der anderen subtrahiren, und die Rest für sich empfinden können. Jede Empfindung präsentirt sich uns als ein Unteilbares." This oft-quoted criticism has been regarded as final. None the less it possesses an inherent weakness which is best exposed by quoting Lewis Richardson's happily inspired parody—" One mountain cannot be twice as high as another. If it could, we ought to be able to subtract the one from the other and to climb up the remainder by itself. Every mountain presents itself as an indivisible lump."

Despite these criticisms, we do regularly make quantitative laboratory experiments in which, for example, it is found possible to arrange a series of grey shades from very light to very dark in what appear to be equal steps, and it is also an experimental fact that a comparison of these shades by photometric methods shows that their objective luminosities are in a geometrical progression ; this, and similar observations, if interpreted in the sense that they justify the Fechner equation

$$S - S_0 = k \log (R/R_0),$$

are apparently in direct contradiction to the criticisms just quoted. How can we escape the dilemma ? Historically, the escape was made by introducing the idea of sense intervals, a notion originally due to Delbœuf, and followed out by later writers. The idea is very clearly formulated by Titchener, who remarks, "the physical . . . magnitude is not a single term but rather a distance between terms. . . . We are apt to say, carelessly, that we have measured ' the highest point ' of Mt. Vesuvius, when we have in reality measured, in terms of our arbitrary unit, the distance between its lowest and highest points. It is not the point that is the magnitude but it is the distance between points. So with sensations ; we are apt to think of a brightness, or of a tone of given intensity, as a sensation magnitude, as itself measurable. Now the stimulus is measurable ; we can measure, in terms of some unit, the amplitude of vibration of the ether or air waves. . . . But the sensation, the brightness or the tone, is just a single point upon the sense scale—no more measurable in itself than the ' highest point ' on Mt. Vesuvius. The only thing that we can measure is the distance between two sensations or sense points."

This brings us to another criticism—that whenever we measure an ordinary physical quantity, we express it in terms of a unit of the same kind, of which it is a multiple or sub-multiple. Where is the unit of subjective brightness or loudness, ask the critics ? Well, we can arrange a series of steps of just noticeable differences, or we can, as we have seen, in the matter of shades of grey, arrange a series of steps of equal-seeming finite differences. It seems to satisfy most writers if these are taken as unit steps for the measurement of sense intervals, rather than as units for the measurement of sensation magnitudes. But it is again doubtful whether this attitude does more than evade the main point.

Most writers on the psychological side base their criticisms on some such fundamental assertion as that quoted earlier from Stumpf. This type of argument may be paralleled from many other parts of the literature. It has one inherent weakness—it does not discriminate clearly between two types of physical magnitude.

Such magnitudes as length, mass, and volume may be very readily conceived as being built up of units spatially juxtaposed in such a way that a unit length plus a unit length gives a length of two units, and so forth. But there are other physical magnitudes of which this is certainly not true, and yet on which quantitative measurements are regularly made. What, for example, is the result of adding, in the sense just used, a density of one to a density of one ? Or a unit temperature to a unit temperature ?

There is a host of such quantities—magnitudes such as surface tension, viscosity, density, diffusion

coefficient, and the like, which are not fundamental magnitudes of the type previously discussed, but may none the less be measured quantitatively. Whether the magnitudes concerned are fundamental or not, a mass, a temperature (not a hotness), a viscosity, even though they may be conceived artificially as built up by the multiplication of a certain unit quantity, do surely present themselves to introspection with the same singularity as does, say, a sensation-brightness.

Moreover (we are now in the region of physical stimuli), even though a physical magnitude X may present itself to introspection as a whole, if we find that X varies with temperature in such a way that $dX/d\theta = f(\theta)$, we have no hesitation in integrating to obtain a functional relation between X and θ, and are led thereby into no contradictions. So, while fully recognising that in one instance we are making deductions from introspection concerning a physical magnitude, and in the other instance from our judgment concerning a subjective sensation, we do not find ourselves led into any morass of contradiction if we regard a just noticeable difference or an equal-appearing interval as a unit of sensation, and artificially regard any sensation magnitude as so many times greater than that unit.

This is, apparently, what Dr. Houstoun does—and in doing so ingeniously avoids difficulties arising from departures from Weber's Law—when he plots $R \div (\delta R/\delta S)$ as ordinate against (log R) as abscissa. Since $d(\log R)$ is equal to $\delta R/R$, it follows that the area included between two ordinates separated by the small interval $d(\log R)$, the x-axis, and the element of the curve is equal to δS. Consequently, if $\Sigma \delta S = S$, the magnitude of the sensation corresponding to any stimulus R, is given by the area underneath the curve up to the ordinate at the point considered. This expresses an important advance. Incidentally, Dr. Houstoun finds that the curve obtained is very closely a Gaussian probability curve.

Other minor criticisms may be briefly noted. It has been remarked that the quantity $S - S_0$ does not represent a difference between two experiences, but an experience of difference. "The expression $S - S_0$ represents a single state of consciousness, the experience of a difference. It admits neither of dissection nor of mathematical treatment." Such a statement is merely dogmatic. Again, criticism of the choice of a just noticeable difference as a unit is contained in the remark that Fechner "regarded a sensation as the sum of a number of just appreciable unit increments of sensation. . . . He maintained that the change of sensation, obtained by adding one ounce to a weight of twenty-nine ounces was absolutely the same as that obtained by adding one dram to a weight of twenty-nine drams. *Of course, were this so, an ounce and a dram should produce an equal sensation.*" The italics are the present writer's. Comment is surely unnecessary.

Dr. L. F. Richardson has approached the matter from a different viewpoint. He endeavours to measure a sensation S "by directly estimating the *ratio* of unequal intervals both much larger than the least perceptible". Thus he has, from 316 observers, obtained estimates of the redness of certain pinks, these estimates being made by putting points on a line divided into 100 equal parts, white being zero, and red 100. The inquiry has been elaborated by mixing on a colour-wheel white and red in different proportions and estimating in the same way the redness of the resulting colour. If X is the position of the mark on the red scale and the angular amount of red (measured as a percentage of 360°) is θ, R. S. Maxwell finds that the results of 35 observers may be represented by $(\theta - 156)(X + 56) = -8736$.

One word concerning the *decibel*. This may, or may not, be used to define a unit of sensation-loudness. The physical measure of the intensity of a musical note of a given pitch rises, apparently, at a much more rapid rate than does the judgment of its sensation-loudness. If we measure physical intensities in, say, micro-watts per square centimetre, we obtain a series of numbers 1, 10, 100, 1000 . . . ., or 10^0, 10^1, 10^2, 10^3 . . . . As a matter of mere convenience it may be advisable to represent these intensities by the series 0, 1, 2, 3 . . . ., and we thus obtain a logarithmic scale of intensities of which the unit has been called the *bel*. One-tenth of this unit is the decibel, and it does happen that this unit corresponds fairly closely to the just noticeable difference of sensation-loudness between two notes of the same pitch at moderate intensities. But primarily the decibel represents a unit of intensity on a logarithmic scale, and need have no more to do with sensation measurements than has a scale of cents in the realm of music.

It is evident that, despite the amount of adverse criticism that has been brought to bear on Fechner's interpretation of Weber's Law, the matter is by no means closed, and that even the long-standing evasion of the difficulties in terms of sensation-intervals may stand in need of revision. The joint discussion between Sections A and J at the York meeting of the British Association should do much to clear up the major points at issue.

Obituary

Mr. H. G. Watkins

The tragic death on Aug. 20 of Henry George Watkins at the age of twenty-five years has removed the most promising and, indeed, the most prominent figure amongst British arctic explorers, a figure as yet too recent to be familiar to those outside a small circle.

The stages of Watkins' rapid advance to the forefront are simply told. At the age of nineteen, while still an undergraduate at Trinity College, Cambridge, he led a summer expedition to Edge Island in the Spitsbergen group. At the age of twenty he spent an arduous year in Labrador with one companion, J. M. Scott, the full story of which

has not yet been written. At the age of twenty-three he led the British Arctic Air-Route Expedition of 1930–31 in Greenland, a venture which is destined to be an important milestone along the road of polar history.

The full significance of the Greenland expedition has probably not yet penetrated the mind of the public, which was intrigued by and slightly critical of the dramatic events which surrounded the relief of Courtauld after his five months' sojourn alone on the ice cap. The narrative, now in the hands of a publisher, will correct some of the misapprehensions and will prove to the readers that here was a new type of expedition, following no former pattern: for Watkins ventured greatly without the lead of tradition; indeed, he constantly questioned the value of traditional methods and devised new and original ones of his own.

Led by Watkins, this group of young and inexperienced men set to work to disprove the wise saws of tradition, to dare great things and to carry them through. In a matter of weeks they were doing what was said to be safe only after years of experience—to drive dog-sledges, to hunt in the Eskimo method, to learn the kayak, to cross the ice-capped continent, to 'live on the land'.

In a crowded year those fourteen men accomplished enough journeys, by air, by sledge, by kayak and motor boat, to be a credit to half a dozen expeditions. A splendid set of men, it is true, but they will all admit that their results were due to the qualities of their leader and to the utter confidence they had in him. Of some of them the world will hear in due course, for they have been trained by the amazing young man whose loss we now deplore.

Of slight build, though strong and supple, somewhat shy and diffident in conversation, there was little in Watkins' appearance to mark him for what he was. Indeed, to the casual glance, his well-groomed figure, his neatly parted hair, his charming but hesitant manner, were signs merely of a pleasant young man who would always follow the precept of others and live quietly but efficiently in some ordinary walk of life. A conversation with him began to awaken doubts as to his being merely that. The alert poise of his head, the quick seizure of essentials, the calm statements of daring plans, all betokened a man of ideas and with the will to carry them out.

Even so, it was not until one saw Watkins in action that one realised his full qualities. It matters not what the action might be, wrestling with a friend, scaling a mountain-side, or, better still, as can be seen in the film of his expedition, 'rolling' a kayak. At one moment he is at ease, smiling and joking, like any other debonair young man; at the next he is tense and alert, head thrust forward, jaws set, and eyes shining with an expression almost grim, balancing his craft for a moment. He flings himself backwards and there is a flurry of paddle and arms, a swirl and a splash, and there he is again, relaxed and at ease, with a shy smile as though he were rather ashamed of his relapse into intense activity.

There must be added to this picture a shy dignity and a charm of manner, a modesty and a thoughtfulness which won all hearts. That is why Dr. H. R. Mill, in his appreciation in the *Times*, used the apt phrase, "so dear a scientific adventurer as 'Gino' Watkins"; that is why his companions would do anything for their leader, and why the news from Greenland has come as the shock of a bullet to his friends. F. D.

News and Views

Function of the British Association

IN suggesting as one reason for the continued success of the British Association the opportunity it affords, in an age of specialisation, for laymen to have intelligent contact with the seekings and findings of the scientific mind and for science to expound its own broad outlook, Sir Alfred Ewing, whose presidential address is printed in our Supplement this week, is on firm ground. The passing of the arrogance characteristic of an earlier age, the widespread belief that there are in science no longer any rigorous laws but only laws of probability, have made for a spirit which strengthens the sense of brotherhood between the scientific expert and the average man, who in his own way is also commonly a seeker after truth. The disappearance of dogma alone should assist the formation of an alliance which is overdue if we are to carry over into human affairs the methods of science and apply the dispassionate temper of science to the solution of our social, economic, and international difficulties.

Progress in Engineering Science

AFTER an engineer's review of the rapid progress in the study of the atom during the last few decades, including the discoveries of the neutron and the splitting of the lithium atom described this year, Sir Alfred Ewing referred to the important contribution of the Association to the advancement of engineering science. Early reports submitted to the Association demonstrated the conspicuous lack of science on the part of early British engineers, and the meagre contributions being made by them to the progress of hydraulics in contrast with the contributions of Italy, France, and Germany. The claim that the British Association by its reports and investigations, its discussions and committees, such as those leading to the establishment of the National Physical Laboratory and international standards for electrical units, has provided an invaluable scientific leaven, few would care to dispute. In his own recollections Sir Alfred Ewing covers the passing of many of the former fairy tales of science into the tissue of everyday life, and in the transition British engineering science has made as important scientific as practical contributions.

The Future of Science

A CONSPICUOUS feature in any such review is bound to be the realisation of the accelerated pace at which

development proceeds once the science has advanced well beyond its nursing stage. The pace of these developments is disturbing only because man is ethically unprepared for the bounty which engineering science has brought him. The world has been made practically instant in its interchange of thought, and international co-operation and brotherhood has become much more than a dream, were man fit for the tremendous moral responsibility which the new gifts and potentialities of life entail. Due to the slow evolution of morals, he has, however, not yet learnt to command himself, to relinquish old habits of thought, sovereignty, independence, which are inconsistent with the command of Nature now put into his hands. If the future is uncertain, at least those whose labours have brought such riches to man may be concerned but not despondent. They cannot but believe with Sir Alfred Ewing that the creative ingenuity which has brought these gifts will yet stir man to achieve in the future the better distribution of leisure and labour and the fruits of labour, which are essential to the continued enjoyment of his new powers. So we find the engineer man of science of the present century voicing the ideals of the great biologist of two or three decades ago.

John Locke, 1632-1704

THE tercentenary of the birth of John Locke occurred on Aug. 29 last, and to mark the event Messrs. J. and E. Bumpas, Ltd., have brought together at the Old Court House, Oxford Street, London, W.1, a well displayed and comprehensive series of engravings, manuscripts, and printed books, including the first edition of Locke's celebrated "Essay on the Human Understanding", as well as letters from Boyle, Newton, Sloane, and other men of his period. The collections are mostly in the ownership of the Earl of Lovelace, having happily suffered no disturbance or vicissitudes since their original assignment within the family. Various special loans that have been received greatly enhance the personal, artistic, and literary interest of the series. Thus, the impressive three-quarters length portrait of Locke, from Christ Church, Oxford, is there, whilst recently Lord Lee of Fareham has sent in an early plaster statuette of Locke, by an Italian hand. A letter from Locke, as a schoolboy, to his father, tells of seeing a "company of Quakers" in Westminster Hall, on business bent, whose leader's hat was "shook off"—recalling that Charles II. removed his own hat in the presence of Penn, explaining that it was the custom at Whitehall for only one person at a time to remain covered.

JOHN LOCKE was proposed for the fellowship of the Royal Society, by Sir Paul Neile, on Nov. 19, 1668, and at a meeting in the following week he was elected and signed the charter book. In that year, too, the illustrious Marcello Malpighi was elected. On St. Andrew's Day, Nov. 30, 1672, Locke was chosen a member of council, and Pepys and Evelyn were brought in at the same time. Earlier in the year, at an ordinary meeting held at Arundel House, Hooke had mentioned his interest in Otto von Guericke's experiments. There was one which he thought deserved to be tried before the Society, namely, that of a sulphur ball, when revolved and rubbed, having a considerable attractive power, and representing the properties of the earth. Mr. Locke, so we learn, intimated that himself had made some experiments with such a ball, and promised that he would bring it to the Society at the next meeting. At that meeting, however (Hooke being present), when he was called upon, Locke excused himself; he had forgotten it, and promised it for the next. Thereafter nothing happened, and, as a matter of fact, Locke's interests in the philosopher's doings were eclipsed by other pregnant interests. He seems, though, to have maintained constant intercourse with Boyle, who signs as "Yr. very affectionate friend", saying he looks up to Locke as a virtuoso.

Report on the Post Office

THE Report of the Committee appointed "to inquire and report as to whether any changes in the constitution, status or system of organisation of the Post Office would be in the public interest" has now been published (Cmd. 4149. London: H.M. Stationery Office, 9*d*. net). The Committee, which consisted of Lord Bridgeman (chairman), Lord Plender, and Sir John Cadman, is of opinion that the total transference of all Post Office communication services to a public utility company or statutory corporation is impracticable, and is neither necessary nor desirable. The Committee considers that the main modification in the status of the Post Office which is required is in respect of its relationship to the Exchequer, and it is recommended that the contribution of the Post Office to the Exchequer should be fixed, for the next three years, at £11,500,000 plus 50 per cent of any cash surpluses in excess of that figure, the residue to be available for the improvement and development of Post Office facilities and services.

As regards organisation, the Committee recommends that the control of Post Office business should be effected through the medium of a functional board presided over by the Postmaster-General. In addition to the Assistant Postmaster-General, the board would comprise four or five members of the Post Office staff, such functions as general operating and supply, engineering and research, finance, and personnel being represented upon the board. A senior permanent member of the board would act as vice-chairman and would be styled 'Director-General', with the duty of ensuring that board decisions were made effective and that continuity and unity of policy were maintained. A decentralisation of administration is recommended under regional directors who would exercise jurisdiction over all the services. Stress is laid on the necessity for fluidity of interchange of staff between headquarters and the provinces. The Committee believes that under these proposals the engineer will be able to play a larger and more effective part in the determination and execution of policy, and it is considered that there should be no bar to a technical officer holding an administrative post, provided he has shown himself to possess administrative ability. Con-

tact with the public will be secured by means of an Advisory Council acting in a consultative capacity, and it will be consulted by the Postmaster-General on questions of general policy. The Report is obviously a document of first importance, and we hope to discuss the Committee's recommendations in due course.

Progress and the Scientific Worker

WITH the great changes inherent in modern civilisation, a new outlook has become essential. Science, the handmaiden of progress, cannot be divorced from industry, administration, social problems, etc.; and with this point of view in mind, the new series of *Progress*, which is being published as *Progress and the Scientific Worker*, aims at giving voice to the new citizenship. Necessarily, therefore, within its covers will be found the joint expressions of the scientific and humanistic outlook. This is made possible since it is the official journal of the Association of Scientific Workers and the British Institute of Social Service. *Progress*, the first bi-monthly number of which is for July-August 1932, has made a splendid beginning. Sir John Russell contributes an informative article on "The Coming Generation". He gives an interesting résumé of recent advances in the agricultural sciences. For example, in the harvesting of an acre of wheat, hand work of olden days involved 32 man hours, the early machine 19 man hours, and the modern machine 4 man hours. But the reduction of these man hours by mechanisation has its drawbacks. On one farm in Norfolk, for example, until recently, 40 men were employed, and now, since its 'mechanisation', only 4 are employed. One of the greatest problems of to-day, which will inevitably be handed on to the coming generation, is the employment of such displaced men.

CLOSELY allied to the problems discussed in this article is the paradox of plenty, which is the subject of an article by Mr. Percy Alden. There is a surplus throughout the world of wheat, cotton, tea, coffee, rubber, oil, and tin. Poverty-stricken countries are no doubt desirous of buying, but the purchasing power is absent. Now, there are, according to Mr. Alden, two essentials to recovery from this world-wide depression: international agreement over debts, reparations, and armaments, and an attempt to settle the currency question which is crippling industry in many countries. The inevitable connexion of industrial development with creative science forms the basis of Sir Richard Gregory's suggestive and illuminating article entitled "Science and the Nation". Sir Richard gives many convincing examples of the 'triple alliance' of creative science, purposeful invention, and skilled labour, and the resulting conditions, which have proved of national and international importance. "Science not only creates new means of existence and new sources of employment by the discovery of new principles and substances, but also places extended use of power at the disposal of every one. . . . Modern technical achievement and scientific thought foreshadow a new economic structure for society in which they should be used to exercise decisive influence upon the major politics of the State as well as upon their administration." Through such activities unbounded possibilities are presented to the new generation, including the problem of the displaced manpower discussed by Sir John Russell. Besides other articles of general interest, the new journal contains scientific, social, industrial, and educational news, reviews, and notes. The price is 6*d*. per copy, and the annual subscription 5*s*.

Mohenjo-daro Dating

A FURTHER stage towards precision in the dating of the prehistoric civilisation of the Indus valley is marked by Mr. Ernest Mackay's letter to the *Times* of Aug. 27. Mr. Mackay records the discovery at Mohenjo-daro of a fragment of a steatite vase which bears exactly the same intricate and very unusual pattern as a double vase of the second period of Susa. It was found at a depth of 28 ft. below datum, very little above water-level in the soil when the river is at its lowest. The inference that it was an import from Elam is borne out by the material of the fragment, a greenish-grey steatite identical with that of the Susa II. double vase. A conservative estimate for the dating of Susa II. would place the Mohenjo-daro find at about 2800 B.C. On the other hand, Mr. Mackay points out that the seal, of undoubted Indian workmanship, found by Dr. H. Frankfort at Tell Asmar, is inscribed with animals which occur commonly on seals and sealings at Mohenjo-daro (although as yet only two cylinder seals have been found) and can be contemporaneous only with the upper levels of that site, occurring at some three to seven feet below datum. This, on the basis of Dr. Frankfort's dating of the Tell Asmar seal, would give a dating of 2500 B.C. for the upper levels at Mohenjo-daro—a reduction on the previous provisional dating. It would thus appear that between the lower levels, 28 ft. below datum, and the upper levels, contemporary with the period of the Tell Asmar find, some three hundred years elapse—a conclusion to which Mr. Mackay states that he already inclined on other grounds.

Protection of Antiquities in France

A QUESTION of much interest to archæologists in general, though naturally of more immediate moment to French archæologists, is raised by Dr. R. Vaufrey in the current issue of *L'Anthropologie* (t. 42, Nos. 3-4), in describing certain steps which have been taken by the Prehistoric Section of the Commission des Monuments historiques for the more efficient administration of the law relating to the protection of prehistoric antiquities. It would appear that French archæologists are feeling some alarm lest they should be on the eve of a condition of affairs prophesied by M. Marcellin Boule more than forty years ago, when he foresaw that, unless effective measures were taken, France's priceless store of prehistoric antiquities in the Dordogne would be exhausted. In the opinion of prominent French archæologists, that time is indeed close at hand. Every effort is to be made to avert it. Present financial conditions preclude anything in the nature of the creation of a department for the purpose, but steps are being taken to secure a stricter enforcement of the existing law. The Prehistoric Section of

the Commission, which is the body responsible, wishes to place no check on scientific excavation, whether by organisations or individuals properly accredited; but it aims at the 'amateur' who seeks to exploit a site for his personal and pecuniary gain. In this praiseworthy object, French archæologists will have the moral support of their colleagues, whatever their nationality, and also in what is clearly their secondary object, namely, to secure the control of the finds—thus averting such a catastrophe as occurred when the skeletal remains found in the caves of Le Moustier and Combe Capelle were lost to France.

Restoration of Roman Bridge, Littleborough, Lancs

ADVANTAGE has been taken of the unemployment problem at Littleborough, Lancs, to invite the co-operation of voluntary workers among the unemployed on the 'dole' in the repair of the Roman road over Blackstone Edge. A part of the work contemplated has now been completed by the repair of the Roman bridge at the junction of Black Castle Clough and Rag Sapling Clough, which carries the road over Black Castle Clough. Some time ago, Mr. J. H. Price of Rochdale directed the attention of the Rochdale Literary and Scientific Society, and through it, of the Society for the Protection of Ancient Monuments, to the fact that the bridge was in danger of being swept away. Mr. Price's examination of the bridge had revealed the fact, which had been completely forgotten in the course of time, that originally it consisted of two culverts, one of which had collapsed and had become completely overgrown with grass. The original length of 25 ft. had thereby been reduced to 12 ft. This culvert has now been restored and the bridge repaired, under Mr. Price's supervision, with the assistance of local firms who volunteered transport, material, etc. The work was carried out with the approval of H.M. Office of Works. Both Roman road and bridge are scheduled as ancient monuments. It is hoped to carry out repairs on part of the road in due course by the same method.

Salamanders and the Pollution of Drinking Water

A CURIOUS and unsuspected source of pollution of drinking-water has just been discovered in Cattaraugus County in western New York State (William G. Hassler in *Natural History*, New York, May-June, 1932, p. 303). Certain spring supplies of water continued to give unsatisfactory laboratory tests even after drastic steps had been taken to protect the springs from outside pollution. Further examination revealed that salamanders, large newt-like amphibians, belonging to four different species, occasionally occurred in the springs, and though a first examination showed that only a small percentage contained the colon bacillus, the investigation was continued. Nearly two hundred purple salamanders (*Gyrinophilus porphyriticus*) were marked with identification discs, and subsequent collecting proved that sometimes individuals wandered as much as sixty-five feet from the stream, apparently in search of food. One was observed eating fly larvæ which were living on mammalian refuse, and this settled the question of how colon bacilli entered the food canals of the salamanders. A second surprise was sprung upon the investigators when they studied more closely the numbers of salamanders in the springs themselves. Purple salamanders were not thought to be particularly common, but repeated nightly visits resulted in a catch of 144 in one spring, which contained about fifty more uncaught. Yet there were occasions when not one of these salamanders could be found, although all the catch was marked and returned to its spring. Laboratory experiments gave some idea of the extent to which contamination might take place. Over a period of 122 days, one salamander excreted a sufficient number of colon bacilli to contaminate 237 gallons of water heavily enough to be considered dangerous on every test. It is believed that the creatures act as reservoirs or incubators, and once infected with colon bacilli, continue to excrete them so long as there is food in the stomach or intestines to supply nourishment to the bacteria.

Fishing with Captive Sucking Fish

MORE than four centuries ago, Columbus observed the strange custom of catching fish and turtles by means of captive sucking fish in the "Jardinellas de la Reina". The general impression has been that these islands were near Haiti and Jamaica, but C. Ralph de Sola points out that a more likely place is the archipelago in the Bight of Manzanillo on the south coast of Cuba (*Copeia*, p. 45, 1932). If this be so, Gudger is wrong in concluding that the original site of the discovery of Columbus "no longer witnesses the exploits of the fisherman fish", for the Siboneyes of southern Cuba, a people of Carib extraction, still practice remora-fishing to a considerable extent. De Sola describes a fishing trip from Matanzas, Cuba. To the under-planks of the boat two sucking-fishes were firmly attached by their discs, and when a turtle was sighted basking on the surface, the fishes were detached and cast as far as possible towards the turtle. The sucking-fishes were themselves held captive by a long thin rope of *majuga* bark, attached in front of the tail, and so soon as they had fixed upon their quarry, the lines were drawn in and the captured hawk's-bill turtle taken aboard. Throughout the proceedings the lines had to be kept taut, and the author states that owing to the arrangement of the lamellæ of the sucker, it is impossible for the remora to relax its hold when tension is placed on its horizontal axis. It is curious that so peculiar a mode of fishing should be found in many distant parts of the world, but Gudger's records from various localities in Africa, Asia, Australia, South America, and the West Indies show that it is almost cosmopolitan in tropical seas.

Eradication of Slugsand Snails

IN a communication to NATURE on the eradication of slugs, which was the subject of a note in these columns on July 16 (p. 90), Mr. Walker Van Riper, 771 South High Street, Denver, Colorado, contributes another method of control based on his own experience. A generous distribution of a solution of ammonium sulphide (1 part in 30 parts of water) killed nearly all the slugs present in his garden in a single

(*Continued on p. 361.*)

Supplement to NATURE

No. 3279 SEPTEMBER 3, 1932

An Engineer's Outlook

By Sir ALFRED EWING, K.C.B., F.R.S., President of the British Association

PRESIDENTIAL ADDRESS DELIVERED AT YORK ON AUG. 31, 1932

AGAIN, for the fifth time, the British Association meets in York, a city of proved hospitality and the stage of great events. York is a monument of history; its very stones are eloquent of the past. Not the least of the episodes it has witnessed was the birth of this Association. We hold York in filial honour and affection. We are nomads who have strayed to the ends of the earth: we have been as far-flung as the British flag. We have enjoyed the welcome of many strange hearths. But here there is nothing unfamiliar. We take delight in coming home to a birthplace of happy memory and in recalling hopes which the past hundred years have generously fulfilled.

Last year the infant of 1831 celebrated its centenary in the vigour of manhood, with a plenitude of pomp and circumstance which demanded no less ample a setting than the metropolis of the Empire. For president we had a man of world-wide fame, who fittingly embodied the imperial aspect that is part of the glory of the British Association. We had long known General Smuts as soldier and statesman: to some it may have come as a surprise when they found him also a philosopher, a student of ideas no less than a maker of history and a leader of men. It would be an impertinence for any successor in this chair to praise General Smuts; to follow him is perforce to follow far behind. But one may congratulate the executive on the happy instinct which recognised that the occasion was unique, and so led them to an unusual—not to say a daring—choice. It was amply justified by the event. Now they have returned to the beaten track along which presidents for the most part plod, and have made a selection for which I am glad to have no responsibility.

Of General Smuts I would say one word more. His occupancy of the chair not only added to the lustre of our rejoicings: I like to think it also had a deeper significance. May we not regard it as a harbinger of the spirit of goodwill and sanity which civilisation longs for, but does not yet see? Our hundred years of science have done sadly little towards curing the nations of mutual mistrust. Surely it was a good omen that, in marking the close of one century of achievement and the opening of another, we should have had for president a citizen of the world whose life has been a lesson in subordinating the lower patriotism to the higher good, who by example no less than by precept has taught his fellows that they should beat their swords into ploughshares and not learn war any more.

Now we revisit our birthplace well aware of our maturity. We have scored our first century and begun to compile our second with the easy assurance of a Bradman or a Hobbs. At once the question arises, Is that assurance justified by the Association's continued vitality? Do we still give the community reason to support us? Or are we a survival, trading on a reputation which our present activities do little to increase? I put the question bluntly—nowadays we are all familiar with disagreeable stock-takings and shrinking values—but it need not detain us long. I am confident you will find no trace of decrepitude. It is true that the sciences included in our purview have become specialised and differentiated to a degree that would make ridiculous any claim to the qualified omniscience which was possible in our

early days. It is also true that each department of science now has its own society of votaries who meet, as it were, in a masonic temple and converse in a jargon that has little if any meaning for the general ear. But these very facts make this Association the more useful. Notwithstanding the restrictions of specialism, science has its own broad outlook, demanding expression and explanation to laymen; and more than ever is it true—far truer than it was a hundred years ago, when we were ridiculed as a hodge-podge of philosophers and made the target of an unsympathetic Press—that laymen want to have intelligent contact with the seekings and findings of the scientific mind.

I say seekings and findings rather than conclusions, for that word has too final a ring. Here we may note a striking change in the temper of the investigator. I am old enough to remember a time when some of the spokesmen of science (never, indeed, the greatest) displayed a cocksureness that was curiously out of keeping with the spirit of to-day. Among contemporary leaders nothing is more general than the frank admission that they are groping in a half-light, tentatively grasping what at best are only half-truths. Things that to one generation seemed to be essential parts of a permanent structure are treated by the next as mere scaffolding. The quest of truth goes on endlessly, ardently, fruitfully. Yet with every gain of knowledge we realise more clearly that we can never really know. To understand, as Einstein lately said, is to draw one incomprehensible out of another incomprehensible. From time to time we discover a fresh relation between observed phenomena, but each of the things which are found to be related continues to evade our full comprehension; and that is apparently the only kind of discovery we can achieve. Our joy in the quest itself never fails; we are constantly learning that it is better to travel than to arrive.

The philosophical implications of this altered attitude are many—indeed they concern the deepest springs of thought. What I wish at the moment to point out is that the new spirit strengthens a sense of brotherhood between the scientific adept and the average man, who in his own way is also commonly a seeker after truth. He listens gladly when the specialist drops his toga and admits that in scientific matters the only dogma is that there is no dogma. Obviously, too, the advance of science makes an increasing claim upon the layman's notice through its technical applications. It invades his home and alters his ways; it affects almost every feature of the daily round; it brings him interests, comforts, wealth; it enormously enlarges his powers of work and play. Further, at a time like the present, when we carry a load of social, political, and economic discontents, the ordinary citizen doubtless reflects that if only we could apply the dispassionate temper of science to the difficulties of the hour, we might face them with less waste of effort and greater likelihood of settlement.

These are a few of the reasons why the British Association keeps its hold on the public. It links experts with one another and with laymen, to the benefit of all. Experts gain by indulging in a short interval of comparatively lucid self-expression. They gain also by trying to understand each other, which is by no means so easy as one might suppose. To meet under these happy conditions is a stimulus to everybody. An old worker in science looks gratefully back on his attendances at the British Association, not only as delightful human events but also as red-letter days in his own development, as milestones in the unceasing march of his subject, and as helps in the hard task of keeping himself more or less in step.

It is recorded that York was chosen for our birthplace because in the Yorkshire Philosophical Society the infant would secure intelligent dry-nursing at the hands of a large body of friendly amateurs. In a letter to the secretary of that Society, Sir David Brewster described the purpose of the proposed Association in the following words:

> "The principal objects would be to make the cultivators of science acquainted with each other, to stimulate one another to new exertions, to bring the objects of science more before the public eye, and to take measures for advancing its interests and accelerating its progress."

There, in a nutshell, is what the Association set out to do, what it may fairly claim to have done, and what it still does. If you want an illustration, you had it last year when a great audience sat for hours, with every sign of sustained attention, while the evolution of the universe was discussed by British and foreign specialists of acknowledged authority, immense learning, and conspicuous variety of opinion.

At the end of that symposium the debate was admirably summed up by Sir Oliver Lodge, the Nestor of physics, who in every sense has filled a big place in our gatherings for more than fifty years. He has taught us much: would that he could teach his secret of perpetual youth! In a recent volume of reminiscences he tells delightfully of the meetings he has frequented and the friendships to which

they have led. If he is thankful for them, so are we for him. Not a few of us have found inspiration in the fountain of his knowledge, in the spontaneity and aptness of his spoken word, in the width of his sympathy and understanding, and have learnt to love him for his large humanity.

My own first contact with these meetings antedates even that of Sir Oliver. Sixty-five years ago it chanced that the Association in its peripatetic course came, for the first time, to my native town, and I was taken, a boy of twelve, by my mother to the Section of Mechanical Science, having already announced my intention of becoming an engineer. To the pundits of Section G, we must have seemed an odd pair, the douce minister's wife and the shy little boy in his kilt. It was by my own wish, of course, that I was taken, and my mother counted no labour lost that might develop intelligence in her family of sons. The boy could not understand much of what he heard ; it was something, however, to see the leonine head of the sectional president, Macquorn Rankine, over whose engineering textbooks he was later to spend many assiduous hours. There is no boundary to a mother's dreams, but in their wildest excursion they can scarcely then have pictured what is happening in this hall to-night.

Here let me make a confession which may also serve as an apology. I have the unwelcome distinction of being the oldest president the Association has ever suffered. In its primitive years the average age of presidents scarcely exceeded fifty : one of them, aged only twenty-nine, afterwards founded the Cavendish Laboratory, and so did a service to science which it would be impossible to overvalue. As time went on, the choice fell on older men, and now the electors have taken what one hopes may be regarded as an extreme step. But, as it happens, this is not the first time I have read the president's address. At the Edinburgh meeting of 1921, the president, Sir Edward Thorpe, was prostrated by illness and asked me to act as his mouthpiece. The small service so rendered brought an unexpected reward. Some newspaper report must have confused the platform substitute with the real president, for a well-known novelist sent me a copy of one of her romances, which was no doubt meant as a tribute to Sir Edward. It was called "The Mighty Atom"—an arresting title. Perhaps that is why I did not read beyond the title-page. Without close examination, it was put by a more orderly hand than mine on a shelf that already held works on like subjects by authors such as J. J. Thomson and Rutherford and Bohr. "The Mighty Atom" was said to be one of the best sellers of its day: in that respect, if in no other, it found congenial company when it was joined on the same shelf by a series of volumes from the fascinating pens of Eddington and Jeans. These, however, I need not tell you, I have read and re-read, to my entire pleasure and partial understanding.

Atomic Physics

If "The Mighty Atom" was an arresting phrase, it was also an apt one. For we now know the atom to be indeed mighty in senses that were little suspected by the begetters of atomic theory. It has been mighty in sweeping away ideas that were found inadequate, in demanding fresh concepts, in presenting a new world for conjecture and experiment and inference, in fusing chemistry and physics into a single science. It is found to be mighty in the complexity of its structure and the variety of radiations it may give out when excited to activity. It has unravelled for us the bewildering tangle of spectroscopic lines ; and, most surprising of all, the atom, however seemingly inert, is mighty in being a magazine of energy which, for the most part, it locks safely away. This is fortunate, for if the secret were discovered of letting loose the atomic store, we should invite dissolution at the hands of any fool or knave. It is also fortunate that in the furnace of the sun, at temperatures far higher than those of our hottest terrestrial infernos, the stored energy of the atom is drawn upon, as we believe, and has been drawn upon for ages, to keep up that blessed radiation which makes man's life possible and is the source of all his power.

In the middle 'nineties there set in an astonishing renaissance of physical science, which has centred in the study of the atom and extends by inevitable logic to the stars. In quick succession came three great discoveries : the X-rays by Röntgen in 1895, radioactivity by Becquerel in 1896, and the electron by J. J. Thomson in 1897. Sensational, puzzling, upsetting, these events inspired every physicist to new activities of thought and equipped every laboratory with no less novel methods of research. A flood of further discovery followed, the flow of which continues unabated. Within the last few months notable items have been announced that well deserve our attention. It may not be inappropriate if I try for a few minutes to touch—however lightly—on one or two aspects of this subject, as it is seen through the eyes of an engineer.

Thanks mainly to J. J. Thomson, Rutherford, and Bohr, we now recognise the atom of any substance

to be a highly complex structure, built up, so to speak, of two sorts of blocks or brickbats—the electrons, which are indivisible units of negative electricity, and the protons, which are indivisible units of positive electricity. It is strangely simple to be taken back, as it were, to the nursery floor and the childish game, and given just two sorts of blocks, exactly alike in each sort, and exactly the same number of each sort, with which to build the universe of material things. The blocks are unbreakable: we cannot produce them or destroy them or change them. In respect of electrical quality the two kinds are equal and opposite, but they contribute very unequally to the atom's mass, each proton (for some reason not yet understood) contributing about 1840 times more than each electron. Every substance is made up of blocks of the same two sorts. If you compare different substances you find that the diversity of their chemical and other properties arises solely from differences in the number and arrangement of the blocks which compose their atoms. Any atom, in its normal or electrically neutral state, must contain an equal number of protons and electrons.

All the protons in any atom are gathered close together at the centre, along with some of the electrons, forming a compact, dense portion which is called the nucleus. Although the nucleus accounts for nearly the whole of the atom's mass, it occupies no more than a very minute fraction of the atom's volume. Those of the electrons which are within the nucleus doubtless serve to bind the protons together; the other electrons constitute, as it were, a voluminous crinoline, or rather a series of crinolines, extending relatively far away from the centre and giving the whole atom an exceedingly open structure. Within that open structure upheavals may be caused by outside agents in various ways. One or more of the electrons in the crinoline may be temporarily removed (as, for example, by the action of heat or by the incidence of energetic radiation), and the atom is then said to be ionised: for a time the balance between positive and negative is upset. But the missing electron returns to its place, or another comes instead, and when this happens a definite amount of radiation is given out, much as energy is given out when a weight falls from one to another landing of a staircase. We may speak of the landings as energy levels. The radiation which issues when an electron falls from one energy level to another constitutes what is called a photon.* It has two aspects, behaving in one like a particle and in the other like a group of waves, and at present we have to accept both though we cannot fully reconcile them. The photon carries a definite quantity of energy and is characterised by a definite frequency of vibration. Its energy depends on the two levels between which the electron falls, and this determines the frequency of the vibration which the photon conveys, for the frequency is equal to the energy divided by that mysterious constant of Nature, the quantum of action discovered by Planck. In any element all the atoms have the same set of energy levels; these contribute to the emission spectrum and account for its groups of spectral lines. In heavy atoms there are many energy levels, and consequently very many lines appear in their spectra.

* We owe the name 'photon' to Prof. G. N. Lewis, of Berkeley, California, who proposed it in a letter published in NATURE of Dec. 18, 1926.

What we have to realise is that all matter consists of the two kinds of electricity, protons and electrons, held apart we do not know how. To the early experimentalists who electrified rods of resin or glass by rubbing them, electricity seemed no more than a curious attribute of matter; now we regard it as matter's very essence—the ultimate stuff out of which every atom is built. If you ask, What is electricity? there is no answer, save that it is a thing which exists in units of two sorts, positive and negative, with a strong attraction for each other, and that in any atom you find them somehow held apart against that attraction, with a consequent storing of potential energy. They are prevented from coalescing, although the difference of potential between them is nearly a thousand million volts. Why they do not flash together is a mystery—one of the many mysteries which physicists have still to solve.

Engineers are accustomed to the idea of storing energy in a condenser by charging the opposed plates to a potential of a few scores or hundreds or thousands of volts. That is done by transferring some of the crinoline electrons from one to the other plate: it involves only a minute supplementary separation, which disappears when the condenser is discharged. In every atom we have a permanent separation of electricities; the protons and electrons look at one another, so to speak, across an immensely greater dielectric gulf which no laboratory operation ever causes them to bridge. That is why every atom is a magazine of energy, the quantity of which (mc^2) is proportional to the atom's mass.

Any of the usual operations of the electrical engineer, such as charging and discharging a condenser or a storage battery, or driving a dynamo

and conducting electricity from it to a distant station where it can actuate a motor or heat the filaments of lamps to incandescence, may be described as the setting up and the breaking down of a comparatively small extra difference of potential between the opposed electricities in some of the atoms of the engineering plant. In every process of industrial electricity, on whatever scale, what happens is a temporary enlargement of the potential difference which always exists between electrons and protons, and then a return to what may be called Nature's *status quo*. But those supplementary differences of potential which the engineer first superimposes and then allows to disappear are exceedingly small, even at their greatest, in comparison with the gigantic difference which the normal condition of the atom itself involves.

A notable event of the year is the strong evidence which Dr. J. Chadwick, of the Cavendish Laboratory, has found for the existence of what is called the neutron—a type of particle in which an electron and a proton are associated in particularly close juxtaposition. There is a like close association between electrons and protons in the nucleus of any heavy element, but it had not previously been discovered in a single isolated pair. Twelve years ago Lord Rutherford conjectured the existence of such a particle, and described the properties it should possess. Its excessive smallness and density, together with its lack of an external electric field, give it a unique power of penetrating matter. It is too slim to be confined under pressure in any vessel: it will simply slip through the walls. The normal hydrogen atom has the same two constituents, one proton and one electron, but in nothing like the same intimacy of association, for the hydrogen atom wears its electron as a bulky crinoline which confers on it an immensely greater volume. The neutron, on the other hand, may be said to have taken the crinoline off, folded it up, and put it in its pocket. Not to be too fanciful, we may at least describe the partners as clasping one another so tightly that the electron has ceased to be a fender; none the less, as a unit of negative electricity it still serves to give electrical balance to the pair. Though so close together, the two constituents of the neutron remain separate and distinct, parted by nearly as many million volts as in a hydrogen atom. In this hitherto unknown particle, the existence of which the experiments of Dr. Chadwick seem definitely to have proved, we have a new physical entity of extraordinary interest and a powerful tool for further research.

Lord Rutherford was the first to discover and name the nucleus. It is the inner sanctuary of the atom, the repository of secrets many of which have yet to be disclosed, almost unapproachable, not only because of its smallness but also because of the electric field in which it is encased. Recognising the nucleus to be a richly charged strong-room, Rutherford has spared no effort to break it open. He has submitted it to a furious bombardment, using as missiles the α-particles which radioactive substances project. These particles, each consisting of four protons and two electrons compactly built together, have the necessary velocity and energy to penetrate to the atom's heart. Rutherford had perforce to fire into the 'brown': he could not aim his gun, nor even tell when it would go off: the chances of a hit were no more than one in many millions. But hits were in fact obtained—hits so effective that they chipped off protons and caused the missiles to be absorbed, thus realising the dream of the alchemist by making one element change into another. That was a dozen or more years ago: since then his attack has lost none of its severity. It has been taken up under his guidance by a school of workers, and many further secrets of the nucleus have been revealed.

Quite recently two of his disciples have gone one better, as disciples sometimes do, to the joy of their lords. Dr. J. D. Cockcroft and Dr. E. T. S. Walton have used missiles of their own making instead of those that come spontaneously and intermittently from substances such as radium or thorium. By beautiful devices they have applied their knowledge of electrical engineering and their mastery of electrical technique to project single protons into the nucleus of lithium, using a steady potential of several hundred thousand volts to give the projectile sufficient penetrating power. An atom of lithium has (usually) seven protons and four electrons in its nucleus; the other three electrons constitute the crinoline. Here again it was a case of firing into the 'brown': out of millions of shots a few reached their billet. When the projected proton forces an entry into the lithium nucleus it creates a domestic disturbance of the liveliest kind. For with the seven protons already in occupation it makes an eighth; the group then splits into two sets of four, each taking two of the electrons, and they fly violently apart with an energy drawn from the atomic magazine. The result is that two helium atoms are formed. This is a notable achievement, the first artificial splitting of the atom by a laboratory process in which there is no recourse to the violent projectiles which radio-

active substances provide. It has been followed up by successfully applying the same method to break up the atoms of other elements.

It is a satisfaction to learn that in all the encounters and emissions and absorptions that are studied among atoms and photons and the parts of atoms there is, so far as we yet know, strict compliance with the accepted principles of conservation in respect of momentum and energy and mass, though matter (in the ordinary sense) is liable to transformation into energy and energy into matter. When radiation is emitted some matter disappears, for the atom that emits it loses a little of its mass; when radiation is absorbed, a like quantity of matter comes into being.

But the engineer finds himself obliged to admit that no mechanical model of the atom can be expected to give an adequate picture of that strange new world. Our mechanical ideas are derived from the study of gross matter, which is made up of vast aggregates of atoms, and any model must share the limitations this implies. It is futile to explain the constitution of the atom in terms applicable to gross matter, just as it would be futile to study the psychology of an individual by observing only the movements of crowds. So we must expect to find within the atom and among its parts qualities and actions different in kind from those we know, and paradoxes which, without a wider vision, we cannot interpret. Such a paradox indeed confronts us at the present time, when we try to harmonise the wave aspect and the particle aspect of the photon, of the electron, and indeed of matter itself. These things are still a mystery—a riddle which some day we may learn to read. Meanwhile we do well to remember that any attempt to portray the structure of the atom in the language of ordinary experience is to give undue significance to symbols and analogies that are more or less invalid. Qualifying phrases like 'so to speak' or 'as it were' cannot be escaped. They are confessions that the image is inevitably a distortion of the reality it is intended to suggest.

Advancement of Science by the British Association

Let us now glance back to the early days of the Association, and trace a little—a very little—of what it has done for the advancement of science, both pure and applied. The two inevitably march together. Between discovery and invention there is, in effect if not always in form, a close partnership with a constant interchange of advantage. No discovery, however abstract, is safe from being turned to practical account; on the other hand, few, if any, applications fail to react in stimulating discovery and providing the experimentalist with more effective weapons of attack.

From the first the Association took cognisance of engineering as one of the subjects it was created to advance. One of its earliest acts, and a very wise one, was to invite reports on the state of science: these were called for in many different fields and were written by the best available experts. In the first batch of such reports were two that dealt with engineering, one on the strength of materials and the other on hydraulics. As it happened, they were of very unequal merit; but they are alike in this, that they demonstrate how conspicuous was the lack of science on the part of early British engineers.

The engineers of those days were big professional figures. They had covered the country with a network of roads and bridges and canals; they had drained the fens; they had built harbours and lighthouses. By multiplying factories, by extending the uses of coal and iron, they were laying the foundations of that commercial supremacy which, so long as it lasted, we took for granted as a sort of national right. They had taught the world how to light towns by gas, and were beginning to drive ships by steam. Above all, they had shown that a new era of locomotion was about to set in. A railway connecting Liverpool with Manchester had been opened: its success was proved, and schemes were projected that would soon utilise labour on a large scale for a host of tunnels and cuttings and embankments, and so relieve the scourge of unemployment which—as we also know—follows the scourge of war. The engineering pioneers were sagacious men who put their faith in experience; they knew little of theory and cared less. Instinct and personality carried them through difficulties of a kind that science might have helped them to solve or to avoid. They had the sense to profit by their own mistakes.

It is significant that in 1832, when the British Association called for a report on the present state of our knowledge of hydraulics as a branch of engineering, the terms of reference included this curious phrase: "Stating whether it appears from the writings of Dutch, Italian, and other authors that any general principles are established on this subject".

The report was written by George Rennie, a son of the greater Rennie who left us a monument of his genius—I wish I could say an imperishable monument—in Waterloo Bridge. After giving a

good summary of the work of foreign theorists the reporter remarks:

"It only remains for us to notice the scanty contributions of our own countrymen. While France and Germany were rapidly advancing upon the traces of Italy, England remained an inactive spectator of their progress."

It is clear that there was much need for the scientific leaven which the new Association could, and did, provide.

Another of the early concerns of the Association was with the performance of steam-engines. At the date of our foundation, more than fifty years had passed since the inventions of Watt provided an engine fit to serve as a general means of producing power. Its earliest application, and still at that date its most common one, was in the pumping of mines. Engineers took a professional and even sporting interest in what they called its 'duty', meaning the amount of water pumped through a given height for each bushel of coal consumed. Nevertheless it is a remarkable fact that neither they nor the physicists of that period had any notion that the process involved a conversion of heat into mechanical work.

It is difficult for us now to imagine a world of physics and engineering where the idea had not yet dawned that there was such a thing as energy, capable of Protean transformations, but in all of them conserving its total amount. Enlightenment was soon to come, and our meeting-rooms furnished the scene. In 1843 Joule brought before one of the sections his first determination of the mechanical equivalent of heat. He spoke with the modesty natural—in those days—to a man of twenty-four. His paper was received in chilly silence. Two years later, after further experiments, he reappeared; but again no notice was taken of the heresies of a youthful amateur. Nothing daunted, he prepared a fuller case for the Oxford meeting of 1847, perhaps remembering that Oxford is the home of lost causes. In a narrative written many years later, Joule has told how the chairman suggested that, as the business of the Section pressed, he should not read the paper, but merely give a brief account of his experiments:

"This [he says] I endeavoured to do, and discussion not being invited, the communication would have passed without comment if a young man had not risen in the Section and by his intelligent observations created a lively interest in the new theory. The young man was William Thomson."

But Thomson, though deeply interested, was not at first convinced. Nearly four years more were to pass before he satisfied himself that the doctrines of Joule did not clash with the teachings of Carnot, of which he was then an enthusiastic proselyte. At length he became a convert; he saw, as we should now say, that the First Law of Thermodynamics was in fact consistent with the Second. Then indeed he accepted the principles of Joule in their entirety and was eager in their support. Quickly he proceeded to apply them to every part of the physical domain. Along with Clausius and Rankine, he formulated the principles which govern the whole art of producing power by the agency of heat. The steam turbine of Parsons, the gas-engines of Otto and Dugald Clerk, the oil-engines of Daimler and Diesel, with all their social consequences in making swift travel easy by road and possible by air, are among the practical results. On the same thermodynamic foundation was built the converse art of mechanically producing cold, which we employ in ever-increasing measure for the import and storage of our food. Joint experiments undertaken by Joule and Thomson led to a further discovery, which later enabled the process of refrigeration to be carried very near to the limit of coldness which Thomson himself established as the absolute zero. In the hands of Linde and Claude the Joule-Thomson effect as a means of producing extreme cold has created new industries through the liquefaction of air and the separation of its constituents by methods of fractional distillation. However cold, however near the absolute zero, was the Association's first reception of Joule, we may claim that in effecting a conjunction between him and Thomson it made amends. Their meeting in 1847 ushered in a new era both of scientific theory and of engineering practice.

Of the Association's many other services there is little time to speak. When the telegraph developed in the middle of last century and spread itself across the Atlantic, largely under the guidance of that same William Thomson (whom later we knew as Lord Kelvin), there were no accepted units in which electrical quantities could be measured and specified. The scientific world was as badly off then for a standard of electricity as the commercial world is now for a standard of value. The need of electrical standards was urgently felt, by none more than Thomson himself. He stirred the Association to act: a strong committee was set up, and in time its work served as a basis of international agreement. There is no danger that any country will wish to 'go off' the standards thus established. To settle them was an incalculable boon to science no less than to technics. It paved

the way for the revolution of the eighteen-eighties, when electricity passed, almost suddenly, from being no more than the servant of the telegraph to be master of a great domain. It was then that the electric light and the electric transmission of power gave it a vastly extended application, and the fundamental discoveries of Faraday, the centenary of which we lately celebrated, came into the kingdom for which they had waited nearly fifty years.

Another notable achievement of the Association was to promote the establishment of a National Physical Laboratory. Informal talks at our meetings in the 'nineties led to the appointment of a committee which moved the Government of the day to take action. The Laboratory was constituted, and Sir Richard Glazebrook was appointed its first head. What it has become in his hands and the hands of his successor, Sir Joseph Petavel, does not need to be told. From small beginnings it has grown to be an influential factor in the world's scientific progress, and a legitimate subject of national pride.

Another by-product of quite a different sort is the memorial to Charles Darwin which we hold as trustee of the nation and of all nations. At our meeting in 1927 the president, Sir Arthur Keith, spoke in his address of the house where Darwin lived and worked, pointing out how admirably it would serve as a monument of the great naturalist. No sooner was the suggestion published than a donor came forward, whose devotion to the memory of Darwin expressed itself in a noble gift. Sir Buckston Browne not only bought and endowed Down House, but also arranged with pious care that the house and its grounds should exhibit, so far as was possible, the exact environment of Darwin's life. The pilgrims who now visit this shrine in their thousands see Darwin's study as it was when the master thought and wrote, and can reconstruct the habit of his days. There could not be a more appropriate memorial. Its custody by the Association involves obligations which are by no means small, and we may claim that they are worthily fulfilled.

One may safely say that there is no department of scientific endeavour our meetings have not aided, no important step in the procession of discovery they have not chronicled. It was at our meeting of 1856 that Bessemer first announced his process of making a new material—what we now call mild steel—by blowing air through melted pig iron. Produced in that way, or by the later method of the regenerative furnace and the open hearth, it soon revolutionised the construction of railways, bridges, boilers, ships, and machinery of all sorts, and it now supplies the architect with skeletons which he clothes with brick and stone and concrete. It was at the Oxford meeting of 1894 that Lodge demonstrated a primitive form of wireless telegraph based on the experiments of Hertz, a precursor of the devices that were brought into use a little later through the practical skill and indefatigable enterprise of Marconi.

At the same meeting there was an epoch-making announcement by the late Lord Rayleigh. His patient weighings of the residual gas which was found after depriving air of all its oxygen led him to the discovery of argon. That was a surprise of the first magnitude; it was the herald, one may say, of the new physics. Next year his colleague, Ramsay, presented other members of the family of inert gases. It is curious to recall the indifference and scepticism with which these really great discoveries were received. Some of the chemists of that day seem to have had no use for inert gases. But the stones which the builders were at first disposed to refuse are become head stones of the corner. In the architecture of the elements they fill places that are distinctive and all-important; they mark the systematic sequences of the periodic law. In a metaphor appropriate to atomic physics we may describe them as coy ladies with a particular symmetry in their crinoline of electrons, unresponsive to advances which other atoms are ready to make or to receive. Inert though they be, they have found industrial uses. Helium fills airships; argon fills incandescent lamps; and neon, so modest a constituent of the atmosphere that you might think it born to blush unseen, has lately taken to blushing deliberately and even ostentatiously in the shop-signs of every city street. In the field of pure science it was neon, outside the radioactive elements, that first introduced us to isotopes; and helium has a greater glory as the key to radioactive transformations and historian of the rocks. Disciples of evolution should be grateful to helium for delivering them from the cramping limits of geological time which an earlier physics had mistakenly imposed.

My own recollection covers many surprises that are become commonplaces to-day: the dynamo, the electric motor, the transformer, the rectifier, the storage battery, the incandescent lamp, the phonograph, the telephone, the internal combustion engine, aircraft, the steam turbine, the special steels and alloys which metallurgists invent for every particular need, wireless telegraphy, the thermionic valve as receiver, as amplifier, as

generator of electric waves. To that last we owe the miracle of broadcasting. Who, a generation ago, would have imagined that a few yards of stretched wire outside the window and a magic box upon the sill could conjure from adjacent space the strains of Beethoven or Bach, the exhortations of many platforms, the pessimism natural to those who forecast the weather, and the optimism of orators who have newly dined ?

"Sounds and sweet airs, that give delight and hurt not.
Sometimes a thousand twangling instruments . . .
And sometime voices . . . that, when I waked,
I cried to dream again."

I know no product of engineering more efficient than that magic box. It needs no attention ; it is always ready for service ; and when you tire of it you have only to switch it off. A blessing on it for that ! Heard melodies may be sweet, but those unheard are often sweeter. Do you ever reflect, when you pick and choose among the multitude of airs and voices, or shut out all from your solitude of thought, that they are still there, physically present, individual, distinct, crowding yet not interfering, besetting you though you do not perceive them, silent until you determine that one or another shall catch your ear ? Go where you will, to the ocean or the wilderness or the pole, you cannot escape that vast company of attendants ; they come to you, unheard, unseen, from every quarter of the globe with a swiftness no other messengers approach. Is any fairy tale so strange as that reality ? In all the wizardry of science surely there is nothing more wonderful than this.

Discovery and the Future of Mankind

Among the inventions which have revolutionised the habits of modern man some were developed by steps that were mainly empirical. Others, especially those that are most recent, have had a very different history : science has been their incubator and their forcing-house. In the advance of any invention there is bound to be an element of trial and error, but when the scientific method is consistently applied the proportion of error is small and progress is swift. We see this exemplified in the development of mechanical flight, where one difficulty after another has been vanquished by aid of well-directed theory and well-related experiment. Or consider that immensely important modern art, the art of communication by telegraph and telephone, by wire and 'wireless'. There the efforts of scientific engineers were dominant at every stage, and it was through their guidance that the art quickly achieved its world-wide triumphs. It is true that in the story of long-distance radiotelegraphy there was a striking episode where the courage of the practical inventor forestalled the discovery of a recondite scientific fact. It happens that the wireless waves from a radio-station, instead of shooting out straight into space as such rays might be expected to do, become bent in the upper regions of the atmosphere, taking a surprising and convenient curvature which enables them to travel round the surface of the globe. An unlooked for kindness on the part of Nature has provided what we now call the Heaviside layer by which she works this happy trick. The strange fact that the rays could somehow bend was recognised and applied by Marconi before anybody had a rational explanation to suggest. Speaking broadly, however, it was scientific nursing of the infant art, and scientific culture throughout its period of growth, that brought it to the splendid manhood which now blesses mankind.

I think we may regard the whole art of electrical communication as an unqualified blessing, which even the folly of nations cannot pervert : in that regard it differs conspicuously from some other inventions. Before it came into use the sections of civilised man were far more separate than they will ever be again. There could be scant sympathy or understanding, little chance of effective co-operation among communities scattered over the earth. A calamity might fall on one and be already old before others knew of it to offer help. Now we have all the world made practically instant in its interchange of thought. Through this physical linkage, which annihilates both space and time, there is opened a possibility of quick discussion, common resolution, simultaneous action. Can you imagine any practical gift of science more indispensable as a step towards establishing the sense of international brotherhood which we now consciously lack and wistfully desire ? Should that aspiration ever become more than a dream we shall indeed have cause to bless the creators of electrical communication, to praise them and magnify them for ever.

In the present-day thinkers' attitude towards what is called mechanical progress we are conscious of a changed spirit. Admiration is tempered by criticism ; complacency has given way to doubt ; doubt is passing into alarm. There is a sense of perplexity and frustration, as in one who has gone a long way and finds he has taken the wrong turning. To go back is impossible : how shall he proceed ? Where will he find himself if he follows this

path or that? An old exponent of applied mechanics may be forgiven if he expresses something of the disillusion with which, now standing aside, he watches the sweeping pageant of discovery and invention in which he used to take unbounded delight. It is impossible not to ask, Whither does this tremendous procession tend? What, after all, is its goal? What its probable influence upon the future of the human race?

The pageant itself is a modern affair. A century ago it had barely taken form and had acquired none of the momentum which rather awes us to-day. The Industrial Revolution, as everybody knows, was of British origin; for a time our island remained the factory of the world. But soon, as was inevitable, the change of habit spread, and now every country, even China, is become more or less mechanised. The cornucopia of the engineer has been shaken over all the earth, scattering everywhere an endowment of previously unpossessed and unimagined capacities and powers. Beyond question many of these gifts are benefits to man, making life fuller, wider, healthier, richer in comforts and interests and in such happiness as material things can promote. But we are acutely aware that the engineer's gifts have been and may be grievously abused. In some there is potential tragedy as well as present burden. Man was ethically unprepared for so great a bounty. In the slow evolution of morals he is still unfit for the tremendous responsibility it entails. The command of Nature has been put into his hands before he knows how to command himself.

I need not dwell on consequent dangers which now press themselves insistently on our attention. We are learning that in the affairs of nations, as of individuals, there must, for the sake of amity, be some sacrifice of freedom. Accepted predilections as to national sovereignty have to be abandoned if the world is to keep the peace and allow civilisation to survive. Geologists tell us that in the story of evolution they can trace the records of extinct species which perished through the very amplitude and efficiency of their personal apparatus for attack and defence. This carries a lesson for consideration at Geneva. But there is another aspect of the mechanisation of life which is perhaps less familiar, on which I venture, in conclusion, a very few words.

More and more does mechanical production take the place of human effort, not only in manufactures but also in all our tasks, even the primitive task of tilling the ground. So man finds this, that while he is enriched with a multitude of possessions and possibilities beyond his dreams, he is in great measure deprived of one inestimable blessing, the necessity of toil. We invent the machinery of mass-production, and for the sake of cheapening the unit we develop output on a gigantic scale. Almost automatically the machine delivers a stream of articles in the creation of which the workman has had little part. He has lost the joy of craftsmanship, the old satisfaction in something accomplished through the conscientious exercise of care and skill. In many cases unemployment is thrust upon him, an unemployment that is more saddening than any drudgery. And the world finds itself glutted with competitive commodities, produced in a quantity too great to be absorbed, though every nation strives to secure at least a home market by erecting tariff walls.

Let me quote in this connexion two passages from a single issue of the *Times* (June 25, 1932). In different ways they illustrate the tyranny of the machine. One is this:

> "The new Ford works built upon a corner of Essex . . . will soon be able to produce motor-cars at the rate of two a minute."

The other comes from Moscow. It also relates to the mass-production of motor-cars, and indicates how Russia is reaching out towards a similar perfection under the austere stimulus of the Five Years' Plan:

> "The Commissar lays down dates for the delivery of specified quantities by each factory and invests twenty-one special directors with extraordinary powers to increase production, threatening each director with personal punishment if deliveries are belated."

We must admit that there is a sinister side even to the peaceful activities of those who, in good faith and with the best intentions, make it their business to adapt the resources of Nature to the use and convenience of man.

Where shall we look for a remedy? I cannot tell. Some may envisage a distant Utopia in which there will be perfect adjustment of labour and the fruits of labour, a fair spreading of employment and of wages and of all the commodities that machines produce. Even so, the question will remain, How is man to spend the leisure he has won by handing over nearly all his burden to an untiring mechanical slave? Dare he hope for such spiritual betterment as will qualify him to use it well? God grant he may strive for that and attain it. It is only by seeking he will find. I cannot think that man is destined to atrophy and cease through cultivating what, after all, is one of his most God-like faculties, the creative ingenuity of the engineer.

Summaries of Addresses of Presidents of Sections*

Physics in the Search for Minerals

PROF. A. O. RANKINE, in his presidential address to Section A (Mathematical and Physical Sciences), entitled "Some Aspects of Applied Geophysics", reviews the development of geophysical prospecting, a practical application of physics which, although originating abroad, has during recent years attracted some attention in Great Britain. The subject is a border-line one between physics and geology, and the complications usually displayed by the underground structures sought demand the combined efforts of physicists and geologists, if reliable results are to be obtained.

It is necessary to distinguish between methods based on definite physical principles and those commonly called 'divining'. Without necessarily condemning the latter, they must be excluded from discussion, since the *modus operandi* is unknown. A geophysical method, properly so-called, must have as its basis the differentiation of some recognised physical property as between rocks, such as density, elasticity, magnetic susceptibility, or electrical conductivity. It involves measuring on or near the earth's surface, by means of suitable apparatus, the physical effects associated, either naturally or through artificial stimulation, with such variations of physical properties.

In dealing first with the gravitational method, a special tribute is due to the work of Baron von Eötvös, the pioneer of geophysical prospecting. The Eötvös torsion balance, designed in the first instance for purely geodetic work, is an instrument of amazing performance. While rendering it robust enough for field work, Eötvös managed to preserve a sensitivity sufficient to allow measurement of gravitational non-uniformities so small as those arising from the rotation of the earth on its axis. The use of such an effective device in investigating density differences of underground formations seems now to be obvious, but it was not until comparatively recently that Eötvös, under the persuasion of the geologist, Prof. de Böckh, agreed, somewhat reluctantly, to turn his attention to problems of economic importance. As a result, the gravitational method of prospecting has since been used very widely. Its principal achievements have been the location and delineation of salt domes with which oil is associated.

The seismic method, although not yet based on so sure a foundation as the gravitational method, has been practised widely on account of its greater celerity, and under conditions which exclude effective use of the torsion balance. As regards the magnetic method, with the portable magnetometers at present available, the method is practically limited to the detection of rocks rich in ferromagnetic material. If the sensitivity of magnetometers could be improved to a degree comparable with that of the Eötvös balance, the scope would be greatly extended; work, therefore, on these lines seems to be desirable.

After a short reference to electrical methods, Prof. Rankine concludes with an appeal for the continuation and extension in Great Britain of research work in the various branches of this comparatively new and difficult subject.

Stereochemistry of Living Matter

In his presidential address to Section B (Chemistry) Dr. W. H. Mills considers "Some Aspects of Stereochemistry". Referring to the electron theory of valency, he explained how, by assigning a stereochemical interpretation to the valency octet, a rule can be obtained which gives an approximate indication of the relative directions of the valencies in compounds to which the octet theory applies. He showed that the 'tetrahedral octet' provides a simple interpretation of the Walden inversion in certain classes of reactions, and that it enables an explanation to be given of the readiness with which *trans*-elimination is effected. He showed also that in the Beckmann transformation, *trans*-migration of the groups is inherently more probable than *cis*-migration.

Dr. Mills devotes the latter part of his address to the problem of the optical activity of living matter. He points out the bearing on this question of the stereospecificity of reactions between molecularly dissymmetric compounds: an optically active substance reacts with unequal velocities with the *d*- and *l*-forms of a dissymmetric compound. Since vegetable organisms can convert their inorganic food-stuffs into optically active compounds, the reactions involved in vital processes must be highly stereospecific. In living matter we find every dissymmetric component present in one configuration only, and these configurations are so correlated that each component encounters that antimer only of its co-reactants with which it interacts the more rapidly. It is evident that living matter thus constituted must be more efficient than

* The collected presidential addresses delivered at York are published under the title "The Advancement of Science, 1932", price 8s. 6d.

a hypothetical tissue in which every dissymmetric component is present in its racemic form.

If we imagine a form of living matter composed of inactive materials, it would consist—by reason of the stereospecificity of vital reactions—of two more or less independent systems working side by side. One of these systems—'the *d*-system'—would include those forms of dissymmetric vital products found in Nature, such as *d*-glucose and *l*-leucine. Working alongside this there would be the enantiomorphous *l*-system. In the growth of vegetable tissue composed of such inactive living matter the *d*-system would be producing the components of the new tissue of the configurations found in Nature, and the *l*-system would be producing their enantiomorphs at an equal rate, and the new tissue would be optically inactive. In a tissue in which one of these systems is in excess, their rates of increase will be unequal. The relative proportions of the components of the two systems in the new tissue will be determined by the complicated laws which connect their rates of production with the concentrations of their generators in the old tissue.

The components of the new tissue will be built up from the food-materials by chains of synthetical reactions, and the rates of formation of the end-products will be controlled by the velocity of the slowest links in the chains. If we imagine a case in which the slowest link is a bimolecular reaction proceeding at a rate proportional to the concentrations of the two reactants, and suppose that the old tissue contained *twice* as much of the *d*- as of the *l*-system, there would be *four times* as much of the *d*- as of the *l*-product in the new growth. We cannot suppose that the relations are so simple as this, but so long as the velocities of the bi- and polymolecular reactions concerned in growth increase with concentration more rapidly than according to the first power (and it seems likely that they will), any excess of one system over the other in the old tissue will become greater in the new growth. An optically inactive growing tissue will then be, in respect of its optical inactivity, in unstable equilibrium. If there is the slightest departure in either direction from exact equality of the *d*- and *l*-components of the tissue, this inequality will increase with growth continuously according to a compound interest law, until eventually the system originally in defect will be completely swamped by the enantiomorphous system.

Given a slight initial bias, an association of complex organic substances which has the property of increasing itself indefinitely at the expense of inorganic substances must necessarily become optically active. If the initial quantity of the association be sufficiently small, the existence of the bias can be accounted for by the laws of probability.

Human Industries and the Ice Age

In the first part of his presidential address to Section C (Geology), entitled "The Contacts of Geology: The Ice Age and Early Man in Britain", Prof. P. G. H. Boswell discusses the training of geologists, and comments on the handicap under which present-day students of geology commence their university careers.

The second and longer part of the address deals with the ice age and early man in Britain. A review of the evidence of successive glaciations and of the intervening episodes makes it clear that a provisional correlation with early human industries can now be attempted satisfactorily. The sequence of these industries, as also of the deposits with which they are associated, is most complete in East Anglia, and the deposits of this area may therefore be appropriately selected as the standard for Britain. This standard succession may be summarised thus: Pre-Chellian and possibly Early Chellian industries, followed by the First Glaciation (Scandinavian Drift, Norwich Brickearth, etc.); First Interglacial interval, lengthy but cold, with extensive valley erosion, human industries doubtful; Second Glaciation (Great Chalky Boulder Clay); Second Interglacial interval, warm, lake-like deposits of Hoxne, Ipswich, etc., valley aggradation and terrace formation, re-arrival of *Corbicula fluminalis*, human industries ranging from Acheulian and Clactonian to Early Mousterian (Levalloisian); Third Glaciation (Upper Chalky Drift, Trail and Coombe Rock); Third Interglacial interval, uplift and valley erosion, Middle to Late Mousterian, and Early to Middle Aurignacian; Fourth Glaciation (Hunstanton Brown Boulder clay), probably Magdalenian.

This succession may be followed through Lincolnshire to Yorkshire and Durham, where the four glacial episodes are indicated by the Basement Till of the coast, the Lower Purple Boulder Clay, the Upper Purple Boulder Clay, and the coastal Hessle Boulder Clay. The Kelsey gravels, containing *Corbicula fluminalis*, appear to lie between the Lower and Upper Purple Boulder Clays. The upper part of the succession is traceable also into Northumberland. As a result of the work of the Geological Survey and of Raistrick and other investigators, the glacial deposits of the Lake District and the southern Scottish ice advances can be

linked up with those of the country east of the Pennines. The advance of the Lake District and Scottish ice into the Irish Sea region and Cheshire plain enables correlation to be made with the Aurignacian deposits sealed in the caves of North Wales, and also with the sequence of events, described by Wills, which accompanied the diversion of the Severn drainage by way of the Ironbridge Gorge. Thus is established a link with the terraces of the lower Severn and its tributaries. The work of Dr. Mabel Tomlinson shows the connexion, via the Moreton Gap, between the deposits of the Avon-Stour system and those of the upper Thames, investigated by Sandford. Correlation can also be effected, though not without difficulty, between the physical and climatic episodes and human industries of the upper Thames and of the lower Thames, concerning which Dewey and Dines have provided useful data.

In general, the relationships of the various human industries to successive glaciations in Britain, as interpreted by reference to a standard succession, show much more agreement than might have been expected.

THE BASIC NATURE OF SYSTEMATICS

The Right Hon. Lord Rothschild has devoted the greater part of his life to the study of species, and, realising that " knowledge begins with the observation of phenomena, not with experiment ", he uses many of these observations and those of other systematists to emphasise the importance of systematics, in his presidential address to Section D (Zoology), entitled " The Pioneer Work of the Systematist ".

The animal world, which appears almost infinite in the number of different forms, presents a picture of life confusing in its endless variety. Yet there is orderliness underlying this seeming confusion, and it is the task of the systematist to discover it and sort out the multitude of organisms accordingly. At the time of Linnæus this was comparatively easy (his " Systema Naturæ " contains fewer than 4300 species); but to-day the task is much more difficult, for not only are many more species already known and being discovered, but a much deeper knowledge of morphology and bionomics is also required. Besides this, the systematists' views have profoundly changed. At the time of Linnæus, marked individual differences were diagnostic of a species, and a species was considered constant. To-day, however, a great range of variability in organisms is known to exist. So profound is this phenomenon that the present-day systematist does not look upon similarity as necessarily meaning relationship, neither does dissimilarity necessarily mean specific distinctness. Variability is an essential character of everything alive; instead of species being constant, they are flexible. For example, the number of specimens of the commonest British mouse-flea (*Ctenophthalmus agyrtes*) required in order to have one pair exactly alike would be several million billions, certainly in excess of the whole flea population of Great Britain. This is tantamount to stating that no two fleas are alike.

The systematist is a direct necessity to defensive and applied biology. Applied biology can only be a science if based on sound systematics. This is evinced in all branches of botany and zoology, especially in their applied aspects, such as entomology and parasitology. The help which the systematist can extend to biology, however, is for him only a side-issue; he is a student of pure science, the driving force in his study of systematics being the irresistible attraction which the subject has for him.

Description, identification, and classification of new species are not the ultimate aim of the systematist; they are merely preliminary. A natural classification is based on blood-relationship, and thus an inquiry into evolution is entailed. Hence systematics involve not only the static study of form but also the dynamic study of development and evolution. A species, in other words, must be read critically and in its entirety—its ontogeny and phylogeny as well as its structure.

The study of certain diagnostic features has resulted in the dividing up of species into geographical races or subspecies. This involves a tremendous amount of new considerations. For example, the individual characters of the ancestral specimen do not influence the formation of a new race; only that which is inheritable and non-pathological is of importance. Then, where two geographical races meet, there may be a strict line of demarcation with no attendant complications, or, on the other hand, there may be interbreeding producing an impure population of subspecies, not strictly distinguishable from, or identical with, either parent subspecies. This phenomenon is another which calls for further investigation.

Other geographical races which the systematist considers identical, though possessing no morphological differences, may have acquired physiological differences, which only experiment can detect. Another possible distinction may be found amongst gregarious mammals which show inheritable likenesses, probably impressed upon the herd by the dominant bull.

Systematics are not concerned solely with species and their variations but also genera and the higher categories, grouped according to relationship, that is, descent.

A brief survey, such as this, of the study of systematics is sufficient to illustrate its complicated nature and the possible ramifications into other branches of pure and applied biology; it demands the best scientific brains—those who not merely float but also dive.

World Reactions to Industrial Revolution

Various types of society, the world over, are trying to graft on to their ancient and traditionalist schemes of life the new scheme of mass-production developed as a dangerous experiment first in England about a hundred and fifty years ago. This reaction to the modern industrial revolution forms the substance of Prof. H. J. Fleure's presidential address to Section E (Geography) entitled "The Geographical Study of Society and World Problems". In vastly increased numbers the peoples of the world, some more, some less touched by the idea of mass-production, are jostling one another as never before, and various types of society have become, willy-nilly, standing dangers to others. In nearly all cases, societies have been in the past nearly self-contained groups, external commerce having been subordinate to internal exchange; and many of the modern groups that gather round a unity of language are attracted to this idea of self-sufficiency, often from fear of economic or political subjection. But diversity of past experience leads them along diverse lines of development, for human societies are primarily associations between men and the earth in particular areas; and must be studied objectively as such, as well as in relation to what they receive from without.

The groups of men who live by hunting, with collecting as an adjunct, were long ago the leaders of the world's life, and the lords of regions that can be determined by finds of their implements as apparently including North and East Africa and South-western Asia, with parts of Europe at times. They are now pressed into far corners in South-western Africa, Australia, and so on, or into the very unfavourable areas of the equatorial forests of the Old World. They have felt the pressure of agricultural peoples spreading from the Euphrates, the Fertile Crescent and Egypt, especially since cultivators and herdsmen have combined in social groups, with the latter as, usually, the ruling element, more markedly so after the horse had become the ally of the ruler.

The spread of the idea of cultivation and herding into inter-tropical Africa met many hindrances from climate, physiography, difficulty of adaptation of crops, fly-belts, phosphorus- and salt-deficiencies, that together kept back social development. Agriculture remained dependent on the hoe as a woman's implement, with the village poor and sometimes only temporary, and no development of cities; with medicine men rather than a more or less learned priesthood; message sticks and the like in place of a written script; and other contrasts all telling against the African, who must be thought of as struggling with special environmental difficulties. But agriculture even in Eurasia long remained traditionalist, though cities, priesthoods, writing, media of exchange, and so on enlarged men's vision; and, in conformity with tradition, this agriculture was usually on a communal basis.

So long as society remained traditionalist, there was implicit in its life the notion of the land as a trust handed along the generations, and that idea has struggled towards larger expression among the peoples who still look to agriculture as their main activity. Among such peoples, notably the French, the notion of stability is thus very strong, and the huge increase of industrial populations, on an essentially unstable foundation, in England, Germany, the United States and Japan, is naturally very disturbing. France has taken up into her strong system a certain measure of industrialist activity. China and India find the corresponding effort far more dangerous to their traditionalist schemes. Africa is waking up to the new contacts and ideas. In fact, the problems of the modern world can be expressed in terms of the multifarious reactions of peoples of diverse experience to the industrial revolution and its schemes of mass-production. But, underlying the diversities of reaction, there is everywhere a growing germ of the idea of economic independence that somehow has to be assimilated by a world policy.

Britain's Access to Overseas Markets

Prof. R. B. Forrester, in his presidential address to Section F (Economic Science and Statistics), directs attention to the increased anxiety over the position of the British export trade. The trade of the world has increased, but Britain's share has diminished. The reasons advanced to explain the slowing down of overseas sales of recent years have

fallen into two main groups. First come those which emphasise the natural course of world industrial development, bringing with it the growth of local industries in many countries; these new efforts, stimulated by the opportunities of the war years, have competed with the British staple exports such as textiles, iron and steel, engineering, and fuel output. Along with these difficulties, there has been the long series of casual misfortunes to which international trade has been subject in the years since 1920, such as restrictive customs tariff policies and the financial, exchange, and currency troubles.

The second group suggests that there is some special retarding cause operating against British export sales which is not present in the case of other countries exporting to world markets. This, it is argued, is to be found in the rigidity of the British income and price structure, which has not proved so adjustable as that of her trade rivals to the falling price levels of international trade.

It is, of course, possible to hold that all these causes are operating, and that Britain may be passing into a phase where the home market is of growing importance and overseas sales of diminishing extent. In the face of these difficulties, it is of some interest to inquire what the evidence is regarding Britain's access to external markets. The evidence of the economic missions which have examined selected markets in which British trade is losing its position suggests that, while price has been the main factor in explaining the decline, the selling methods require close examination and revision; adequate, no doubt, at a time of British predominance, they seem in need of alteration and adjustment to meet new forms of competition. It is also doubtful if the structure of the overseas distributive organisation is adequate to carry the increased tasks which must be undertaken to push British trade, and certain suggestions are made to meet this difficulty.

The position with regard to tariffs is considered only to see how far Britain is at any disadvantage compared with her trade competitors in gaining access to overseas markets. The central feature of her policy within recent times has been the unconditional interpretation of the 'most favoured nation' clause; this has in general guaranteed to her, entry of her goods exported at the lowest available rates of duty in the tariffs of other countries. It seems doubtful, however, how far this is now an adequate method of dealing with the world tariff situation, and to gain favourable access to external markets Britain may have to join tariff groups and employ group treaties to secure her position. One of her chief difficulties is that, like Germany, her exports are to so great an extent finished goods.

Britain is working her way to a new equilibrium between home and external markets and to a new proportion in the relative importance of her overseas markets; she could certainly strengthen her position in overseas areas by improving her means of access in selling method and distributive organisation, as well as in directing her policy towards the creation of low tariff groups.

The Call to the Engineer

The engineer and scientific worker have shown the way to plenty. All the material necessities and comforts of life, with our known methods of manufacture and transportation, could be produced and distributed in sufficient quantity to make the inhabitants of the world ten times more wealthy than they are on the average to-day. That is the claim made by Prof. Miles Walker in his presidential address to Section G (Engineering), entitled "The Call to the Engineer to Manage the World".

Civilisation has been extending for centuries, and the application of steam power to manufacture has been in operation for one hundred years, yet by far the greater portion of the inhabitants of Europe and America are very poorly supplied with the things that make life full, free, and enjoyable. If we go outside the modern States to the teeming millions of China and India, we find that only a little has been done to improve the lot of the peasant, who still lives by bodily toil, and receives no share of that fullness of life which we know to be possible when the machine lightens our labour and education opens the mind.

The great difference between what is possible and what has been achieved is in a great measure due to the incompetence of the rulers. The men who get into positions to control towns, provinces, and States the world over are very seldom men of real ability. They are talkers rather than doers. They have not undergone any test to show whether they can arrive at a logical conclusion from a given set of premises. Though there are brilliant exceptions, as a class they have neither the education nor the mentality for their job.

Contrasting the way in which things are managed in a great engineering undertaking with the way in which things are muddled in the world at large, we are led to believe that if the engineers (in which term, for brevity, may be included all scientific men) took a greater part in world management, they would make a greater success of it. In this

world crisis there is a call to the engineer to manage the world.

One of the main things wrong with the world is that there is no proper plan to enable the people to make use of what science has made available. Men's efforts are mainly directed at buying and selling at a profit instead of being directed to the making of things they want, and distributing them in the least expensive way.

Two improvements that the application of scientific methods would effect would be the avoiding of trade slumps by the adjustment of prices and the avoiding of labour troubles by giving the arduous tasks to all the young men and women irrespective of rank.

At times when trade is supposed to be good, things are sold at three or four times the price paid to the people who make them, and as a consequence the people who make them cannot buy them, so there is a slump in the market. This is the main reason why there is so much unemployment and want in the United States, where food, raw materials, capital equipment, and everything for the production of wealth is in abundance. If prices were adjusted so as to cover the exact cost of manufacture and distribution, then the people concerned in the manufacture and distribution would receive enough money to buy them. They would make more and buy more, and wealth would increase. But the slightest illegitimate profit renders it impossible for the people who make the things to buy all that they have made. The demand necessarily becomes smaller and smaller, and wealth decreases.

Prof Walker suggests that the Government should found an experimental self-supporting colony under the auspices of engineers, scientific workers, and economists. The object in view would be to ascertain how far it is possible, with our present knowledge and the best methods of manufacture and distribution, for a group of, say, a hundred thousand persons to maintain themselves and to increase continually their wealth when freed from the restraints and social errors of modern civilisation. Such an experiment might do more to enlighten the world as to the possibility of modern logical methods than an experiment carried out on a continent thousands of miles across, where unforeseen difficulties might easily defeat the best intentions. If we ask what differences there would be in the old world and those of the new colony from which so much is to be hoped, Prof. Walker, in partial answer, would draw two pictures. One is that of a feeble man of sixty years working all day in a sewer, because it is the only occupation he can find to earn his daily bread. Far worse, to him, than the unpleasantness of the task is the rankling injustice that he should be compelled to do this job for no more reward than a living wage, while others with easier tasks get greater rewards. The other picture is that of a young man of twenty-three years, who has chosen the task of sewerman in the spirit of those who went to the trenches in 1914. 'Sir Sewerman', aided by modern appliances, cheerfully puts in his three hours of unpleasant work, and for the rest of the day disports himself and extends his education.

So with all the work of mankind; it can be done cheerfully when justice seasons its incidence.

The Development of Archæology

The subject of Dr. D. Randall-MacIver's presidential address to Section H (Anthropology), is "The Place of Archæology as a Science and some Practical Problems in its Development". It is a very happy and propitious moment for the discussion of the place of archæology as a science and the practical policy which we ought to pursue in view of its startling and wide development. We need to devise methods of organisation, to think out means of collaboration, and to subdivide the field of our activities so that they may all be related in a conscious scheme.

Archæology is very closely related to anthropology; but, whereas anthropology is the wider of the two, the interest of archæology is solely in those works which can only be produced by man when he has become more or less *sapiens*. Without anthropology, however, archæology would be blind in one eye and very short-sighted in the other. What archæology discovers is the bare fact; it can never divine the essence of the fact, which gives it all its meaning and interest. For the whole meaning and rationale of man's life we are necessarily dependent on either anthropology or history.

Documentary evidence is very limited in its range, and although occasionally it usefully supplements our anthropological knowledge, its principal and indispensable function is that of affording a time-scale, which cannot be provided from any other sources. For the immeasurably remote periods of prehistory, geology provides a rough time-scale, which, however, is steadily being improved. About 3500 B.C. this clumsy instrument can be replaced by a much finer one derived from inscriptions and documentary evidence. This is the period of protohistory. But archæology does not end where history begins; and all through the

classical periods of Greece and Rome, and all through the Middle Ages, history needs and receives the greatest assistance from archæology.

Turning to the organisation of archæology, this may be treated under three heads: the collection and recording of the material; the housing, conservation, and exhibition of it in museums; and the comparative study of all such material and the digesting and disseminating of the results in books.

As to the policy and necessities of the science in the collection of the material, there are one or two axioms which once were generally ignored. Of these the most important is that no person who is not qualified by special knowledge and study should ever be allowed to excavate at all, with the corollary that the excavator should be accredited by a properly constituted institution or committee. The looting of sites for the profit or amusement of a private individual will never be allowed again by any government. It ought to follow that digging for antiquities even by the owner of an estate should be forbidden. It is to be regretted that there is no scientific League of Nations, to which we might appeal for protection against powerful interests, whether individual or political.

It is the duty of the explorer to study and record whatever he finds. It is not quite so invariably part of his creed that he should publish, and that quickly and fully. Nothing—no display of plans, photographs, etc., however elaborate—can take the place of publication. A further principle is that a portion of every site should be reserved for future study. The wisdom of one generation, even our own, is unable to foresee all possible problems.

The archæologist's activities in museum work are to a great extent governed by considerations of space. It is said that the public does not want museums; but granted certain exceptions, this is the fault of the museums, in which the visitor is left to drown in an uncharted sea.

In regard to the dissemination in books of the knowledge gained by excavation, the original scientific account is written for the professional and should give a precise account of every stage of the excavation; but when the seed has been gathered and sown, it has to be watered. The semi-popular account may be undertaken by the original explorer or others. Lastly comes the general synthetic works of the writers who manufacture our fine fabrics out of the raw material; for the most striking thing in the archæology of recent years is its sudden co-ordination. The ancient world now appears as a connected whole; while time, thanks to the work of Sir Arthur Keith, Prof. Elliot Smith, and others, has shrunk no less than space. In this synthetic work, however, although the archæological imagination may find play, it must adhere to types of reason which may be regarded as conditionally valid.

Theories in Psychology

In the first part of her address to Section J (Psychology), entitled "Current Constructive Theories in Psychology", Prof. Beatrice Edgell refers to the tercentenary of the birth of John Locke on Aug. 29, 1632. His "Essay Concerning Human Understanding" is primarily a theory of knowledge, but is full of psychological interest and rich in illustrations which would now figure as child, animal, or comparative psychology.

At the time at which Locke wrote, it was impossible for a writer to draw the distinction between a logical analysis of knowledge and a genetic account of knowledge in the individual and the race. Locke's 'simple' idea stands sometimes for an ultimate constituent of knowledge, for a category of the understanding, and sometimes for primitive sensory experience; consequently his 'plain historial method' is misleading. Side by side with his doctrine that knowledge is the perception of the agreement or disagreement of ideas, Locke left a theory of the chance connexion of ideas by their association in time, a linkage which repetition can so strengthen that it comes to be regarded as 'natural', that is, intrinsic. This theory was only put forward in the fourth edition of the essay, and was given as an explanation of error and prejudice. From it and from the doctrine of simple and complex ideas arose the association school of psychology, which culminated in James Mill's "Analysis of the Phenomena of the Human Mind", 1829.

Implicit in the confusion of logical with psychological analysis and in the disparity of the two unreconciled principles of knowledge, intrinsic relation and temporal sequence or coincidence, lie the lines of cleavage which are clearly manifest in the diverse constructive theories put forward to-day. Behaviourism is association psychology in a physiological garb. Advance from simple reactions to complex conduct is ascribed to 'conditioning', and conditioning turns on the sequence of stimuli. Psycho-analysis likewise relies on temporal association as a constructive principle, though the theory is grafted on to the root doctrine of the school, the unconscious with its emotions and instincts. The method, which gives this school its name, is not free from the confusion of psychological with logical analysis. *Gestalt* psychology strives to

break away from the atomism characteristic of the association tradition. It detects the baleful influence of a doctrine of elements and compounds both in behaviourism and in the existential school of Titchener and his followers. In place of sensations as simple elements, the *Gestalt* psychologist recognises sensory patterns as simple wholes (*Gestalten*). In place of association, it preaches 'organisation'. The Neogenetic principles, put forward by Prof. Spearman as basic for any theory of psychology, assert, in agreement with Locke's definition of knowledge, that all knowing is a knowing of relations.

These divergences of theory are to be welcomed. Advance may be looked for not in the victory of one theory or method over all others, but in the discovery of the sphere appropriate for each. Every theory is recognising some aspect of truth. Adherence to a particular school ought not to blind a psychologist to an aspect of fact for which a rival theory offers a more adequate explanation.

In the second part of the address this thesis is illustrated by data from some experiments on memory recall.

Growth Processes in Trees

Many recent studies of growth in trees have added considerably to our knowledge of the various activities closely connected with arboreal development, and such considerations formed the basis of Prof. J. H. Priestley's presidential address to Section K (Botany) entitled "The Growing Tree".

One important recent discovery is that growth each season begins in the bud, whence it spreads downwards over the rest of the tree. These buds, of course, produce new shoots which grow in length, while the older branch systems thicken. Thus, growth in length and growth in thickness (radial growth) are intimately connected. Radial growth is dependent upon the activity of meristematic cambial cells, and this cambial activity only begins as the buds commence growth and then spreads downwards from the base of the buds. For this reason, when pruning, the stem should be cut just above a bud, for if a long piece of stem be left above a bud, since the cambium in it cannot resume activity, this stem withers to an unsightly projection.

The activities underlying growth and development are of importance in the comparison of the hardwood and softwood trees. The hardwood are dicotyledonous (Angiosperms), whereas the softwoods are chiefly coniferous (Gymnosperms). In softwoods, with the 'Christmas tree' habit of branching, radial growth begins below the buds and spreads downwards, but the lower and more shaded the branch, the slower radial growth activity spreads down it. Therefore cambial activity in the main trunk around the bases of the lower branches begins before it does on the branch bases themselves. Thus the old wood of the branch becomes gripped in the new wood of the trunk without actually becoming joined to it. Only later, as cambial activity on the branch begins, do branch and main axis join in forming a common sheet of wood. Therefore, in a thin softwood plank, the wood of the branch may lie loose in the wood of the trunk and knots may even fall out. In the hardwood, branching is by no means so regular, and cambial activity at a branch base begins about the same time as that of the main axis on the same level. Thus a common layer of new wood is formed at the beginning of renewed growth activity, with the result that knots in a plank of hardwood are fixed firmly in the matrix of main-stem wood.

Differences in the microscopic structure of softwoods and hardwoods are closely connected with differences in cambial activity. The cambium cells in the softwood are very long and thin with pointed ends. All new cells cut off from them are similar, very long cells, which expand, by absorbing water from the old wood, with great regularity, all cells in the same zone differentiating at the same time and in the same way. The result is the formation of a very regular woody tissue consisting only of narrow pointed tracheids. In the hardwoods, the cambium cells are much shorter and have relatively transverse end walls. The new tissues derived from this cambium have similar cross walls, and when these short cells expand with water, great strain is thrown upon these cross walls. A new 'strip' method of studying the development of these tissues has shown that as these cells expand, the cross walls collapse in some of the young cells. These cells immediately expand very widely; the walls then break down almost simultaneously in long files of cells in vertical continuity, and the result is the formation of vessels. This rapid expansion of cells in vertical files in the new tissues leads to a diversified structure in the wood finally formed. As the vessel segments expand, they compress cells around them, which are still in a plastic stage, and later form pointed fibres longer than the cambium cells from which they were originally derived. The differences in hardwood and softwood anatomy can thus be traced very largely to the original

difference in length of the cambium initials from which these tissues are derived.

These characteristic growth processes necessarily have a direct bearing upon such problems as the movement of water in the wood and the translocation of food materials in the bast. Water is attracted by osmotic forces into the growing regions around the cambium and the buds. The old wood acts as a water reservoir. But the water is withdrawn more quickly than it is replaced, especially as transpiration from the expanding foliage becomes vigorous. The result is a state of tension, first in the outermost part of the old wood, then in the first formed elements of the new ring of wood. This tension is usually regarded to-day as sustained by liquid columns in the tracheal elements. But experiments are described in which liquid rushes up these tracheal elements when they are immersed and cut open, which suggests that many of the tracheal elements contain nothing but water vapour. In this way wood can be injected to great vertical distance in a very short time, if the liquids, like water, can pass the cross walls. This fact may not be without its practical application where trees have to be killed completely, as in clearing belts of country against the tsetse fly in tropical Africa.

Present-Day Teaching of Elementary Science

At the outset of his address to Section L (Educational Science) Mr. W. M. Heller discusses the functions of the Section. A generation ago it concerned itself with the place and character of school science, but of late years it has adapted itself to the study of the embryonic development of a science of education. He considers it more useful to record the convictions that remain from long contact with problems of teaching, inspection, and administration than to venture into the field of general educational philosophy. He sees great increase in the machinery of school science, but has grave doubts as to the design and efficiency of the machine. In elementary education we have not yet taken science seriously, and in future we must regard it as of the same fundamental importance as the three R's.

Curricula and methods are dominated still by men of unpractical upbringing and with little knowledge of or sympathy with the possibilities of scientific method and thought. Ignoring the change in the position of the mass-centre of human knowledge that has occurred during the past century, a blind faith persists in the grammarian tradition based upon a false and narrow conception of culture.

Without neglect of mental and æsthetic development, education must, in the broad sense, be directly and indirectly vocational. We must cater for the boy and the girl leaving school at fourteen, at fifteen, and at sixteen years of age, and must endeavour to place them in a position to face with success the employment and the problems that will confront them. No general school examination can direct usefully the various types of training necessary. The yoke of examination appears to hang more heavily than ever upon the shoulders of the teachers, who patiently accept the burden as part of a preordained scheme of things. In the years that need greatest concentration upon those aspects of training that no ordinary examination attempts to test, the evil spirit of external examination has obtained a stranglehold upon the efforts of both teacher and pupil. The problem of external examination is not unsolvable, but it must be faced with courage, and we must trust our teachers. Internal examination associated with sufficient and constructive inspection can provide every safeguard that the public can demand.

The term 'heuristic method' should be discarded, owing to the intemperate and destructive criticism that has centred around it; but tribute should be paid to the inspiration of Prof. H. E. Armstrong, who almost alone during the past fifty years has helped educationists to put purpose and method into their work. The term 'natural method' is adopted as less open to misinterpretation than 'heuristic method'. A broad course of general science is essential; the artificial barriers between subjects set up for the convenience of external examinations must be broken down, the teacher must be free, if necessary, to touch half a dozen sciences in one and the same lesson. The lack of progress in general science is due to the narrow specialisation of students in the university, and this is reflected in the schools by the absence of useful and vocational purpose. The training of the future science teacher needs radical change, and more deliberate purpose; he should be able to teach efficiently any section of a general science course; he must be a far more handy-man in every sense of the word than the present university output provides.

The historical and philosophical treatment of education does not produce practical and resourceful teachers, and theoretical training would be more effective if undertaken after some years of thoughtful experience. The art of teaching must develop

along inductive lines; we must concentrate upon a product equipped to gain knowledge from experience and conscious that success in his art can be achieved only by his own investigation.

Less advance has been made in domestic science than in other practical studies. Domestic duties call for more intelligence, knowledge, and initiative than do the vocations followed by boys. The academic courses that boys usually follow make little appeal to girls. There is need for better correlation between the teaching given in the laboratory and the kitchen, and we shall not get the best out of either of these aspects of domestic science until both are taught by one and the same person. Neither the university nor the domestic training school are turning out the right type of teacher.

The address of the previous occupant of the Section's chair at York—Sir Michael Sadler—recalled the traditional ruts in which education moved, the concentration upon book-learning, the neglect of handwork, and our wastefulness of the more ordinary kinds of intellectual material, which were regarded by Sir Michael as the besetting weakness of the time. He deplored the worship of examinations as destructive of teaching and learning alike; but he did not foresee the extent to which machine-made examination would divert from its proper purpose the major part of our educational effort.

Sheep Farming in Great Britain

Sheep farming is usually associated with ranching systems in zones beyond the areas in which cultivation and dairying are economically possible. Yet Great Britain occupies about the eighth place in a list of the countries of the world arranged according to total number of sheep, and it is only surpassed by New Zealand as regards density of sheep population. The great importance of this branch of British agriculture forms the basis of Prof. R. G. White's presidential address to Section M (Agriculture), entitled "Sheep Farming, a Distinctive Feature of British Farming". Compared with other European countries, we have many times the number of sheep per unit area of agricultural land.

This special importance of sheep is no new feature of British agriculture, and it has had profound effects on our national life as well as on our agricultural organisation. During the Middle Ages, continental manufacturers looked to Great Britain for their supply of wool, just as the Yorkshire manufacturer now goes to Australia. Until the latter half of the eighteenth century, wool production was much the most important function of the national sheep flock. Meat production became more important during the eighteenth century, when the demands of the increasing urban population and the introduction of roots and clover altered the whole basis of British agriculture. During the last thirty or forty years there have been great changes, largely resulting from the development of the fat lamb industry, but also in great measure due to the low prices of grain.

These changes have resulted in great modification of the composition and distribution of our flocks. On light land in the south and east of England, 'arable sheep' managed on a very intensive system play an important part in maintaining the fertility of the soil for corn growing. So much land has been laid down to grass, or is now cultivated on a different system, that the total sheep stock in these areas has been reduced by more than fifty per cent. Although there have been large increases in other districts, for example, North Wales and the east of Scotland, they by no means provide full compensation for the loss. To a very large extent, our sheep stock consists now of hill breeds and their crosses, which are kept on an extensive system involving little outlay on labour, feeding stuffs, or permanent equipment. Their substitution for arable farming has brought about a general decline in the life of the countryside.

On the other hand, at the present time sheep provide the only possible way of utilising the large areas of hill land economically, and an outlet for the draft ewes and store lambs is essential. Moreover, grass sheep, managed in such a way as to meet present demands, fit in well with grass production, for which the climate makes the greater part of Great Britain best suited.

Possible developments include a consideration of the practicability of securing a greater return per unit of the flock; possible changes in management and functions; and the highly controversial question of the need for maintaining our great number of different breeds. The diseases of sheep are of great importance to flock management, and in this connexion there is an urgent need for more research.

Printed in Great Britain by R. & R. Clark, Limited, Edinburgh.

application, and no injury to any of the plants was observed. Although no special apparatus is essential, the following method for distribution is suggested. A water suction pump (ejector) is attached to the garden tap, and hose piping leads from the suction opening into the barrel containing ammonium sulphide solution. The distributing hose is connected to the other end of the filter pump. On turning on the tap, the solution is drawn off from the barrel, mixed with water from the tap, and forced through the distributing hose. Calculation and trial are of course needed to determine the strength of ammonium sulphide solution in the barrel in order to yield 1 part in 30 in the distributing hose. Mr. Van Riper would welcome the reports of other experience in the use of this method for slug eradication.

Narcissus Pests

BULLETIN No. 51 of the Ministry of Agriculture and Fisheries (May 1932), entitled "Narcissus Pests", by Mr. W. E. H. Hodson, has recently come to hand. The object of this publication is to provide growers with reliable and up-to-date information enabling them to control the more common and destructive of the enemies of the narcissus. The Bulletin deals with the species of flies of which the larvæ are persistent enemies of the bulbs, while eelworms, mites, and other pests are also fully discussed. The most satisfactory treatment for all such pests is the submersion of the bulbs in water maintained at a temperature of 110° F. for three hours. If such treatment were not available it is highly probable that the bulb eelworm would by now have rendered commercial growing almost impracticable. The Bulletin is obtainable, price 1*s.* net, from H.M. Stationery Office or through any bookseller.

Penguins' Eggs

THE appearance of the eggs of penguins in some of the large London stores, where they were sold as epicurean novelties at ten shillings a dozen, led the Royal Society for the Protection of Birds to make inquiries regarding the source and supply (*Bird Notes and News*, vol. 15, No. 2, p. 39, 1932). The eggs were those of the Cape or black-footed penguin (*Spheniscus demersus*), and were obtained in one of the extensive penguin rookeries in the Cape Province of the Union of South Africa. The eggs were collected for sale under Government regulation, and the Trade Commissioner for South Africa informed the Society that during the months of April and May of the present year some 2000 dozen of the eggs were exported to Great Britain. We hope that the Government department which regulates the taking of the eggs will see to it that the strength of the penguin colony is not too seriously reduced, remembering the fate of the gare-fowl when commerce invaded its innumerable hordes; and we trust that the exceptional opportunity will be taken of associating the statistics of eggs taken with the total strength of the colony year by year, for the study of the effect upon the population of the colony as a whole.

Monument to Laplace

THE issue of *Revue Scientifique* for Aug. 13 briefly records the inauguration on July 3 of a monument to the great French mathematician, Laplace, at his birthplace, Beaumont-en-Auge (Calvados). The monument, which is the work of M. R. Delandre, has been erected by international subscription, among the principal contributors to which were Messrs. J. H. Fry and J. Flanagan, of the United States, and the two Carnegie Foundations for Science and Peace. The unveiling took place in the presence of Maréchal Franchet d'Esperey, of the Société de Géographie of Paris, and distinguished representatives of the Academy of Sciences, the Paris Observatory, and the École Polytechnique. As recorded in NATURE for April 2, 1927, p. 493, at his death in March 1827 Laplace was buried in the Père Lachaise cemetery in Paris, but sixty-one years later, in 1888, his remains were exhumed and reinterred in the grounds of the family estate at the little hamlet of Saint Julien de Mailloc, situated between Lisieux and Orbec (Calvados). At the time of the reinterment, the monument which had marked the resting-place of Laplace in Paris was presented to the commune of Beaumont-en-Auge, and was re-erected in the cemetery there.

Discovery of the Deviation of the Compass

IN the July issue of *Science Progress*, Mr. N. H. de V. Heathcote brings together the data at present available for fixing the date of the discovery of the deviation of the compass from true north. The figure in the instructions of the Nautical Chart of Bianco of 1436 which has been taken as evidence that a correction for a deviation of 18° west of true north was allowed for, the author concludes has nothing to do with deviation. The first definite record of deviation he considers to be that made by Columbus in September 1492, during his first voyage across the Atlantic. In his record of his return in 1496 from his voyage to India, Columbus mentions Flemish compasses which read $11\frac{1}{4}$° west of north when the Genoese compasses read north. Mr. Heathcote points out that pocket sundials were in use in Germany about the middle of the fifteenth century which were set in the meridian by a compass; in the latter an allowance for a deviation of 6° east of true north was made, while in Etzlaub's road map of Germany of 1492 instructions are given for orienting it correctly by compass, an allowance for deviation of $11\frac{1}{4}$° being made. He concludes that pocket sundials with an arrow set $11\frac{1}{4}$° east of north were familiar objects in Germany before the time of Columbus.

Bibliography of Line Spectra

No better comment could be made on the present importance of line spectroscopy than the publication by the American Physical Society in *Reviews of Modern Physics* (April) of a bibliography of the papers which have appeared between 1920 and 1931. This has been compiled by R. C. Gibbs, and is prefaced by a short elementary account of the interpretation of spectra. The bibliography is divided into three sections. The first, which contains the majority of the references, is a list of those papers which contained new data or discussions; these are divided according to elements, stage of ionisation, year of publication, and alphabetical order of authors, and in general, when one paper has dealt with several elements, it

has been listed under each to avoid cross-references. The two other sections are much shorter, and deal with more general publications, articles mainly concerned with the mathematical machinery of quantum mechanics not being included. The lists occupy some 150 pages of small print, and although essentially uncritical, should be of the utmost value to all workers in spectroscopy.

Progress in Modern Physics

IN his introduction to a set of pamphlets on recent developments in physics ("Exposés de physique théorétique") published by Hermann et Cie, of Paris (6 francs each), Prof. L. de Broglie raises once more the question of how contact can be maintained between workers at different branches of physics. It is now quite impossible for any one person both to read critically all new papers, in any but a most limited field, and to advance the subject himself. Realisation of this is, of course, not new, and has inspired, amongst other publications, the American Physical Society's *Reviews of Modern Physics*. The present series seems likely, however, to fulfil its purpose better than anything that has gone before. Although definitely for advanced workers, the articles are anything but abstracts, being well written and critical, and containing adequate detail without providing what is really irrelevant to anyone not a specialist in the particular subject dealt with. They also deal with relatively new or very recent work. Of the two at present under notice, Prof. de Broglie's is based on Landau and Peierl's treatment of the uncertainty principle (*Z. Phys.*, vol. 69, p. 56), and is purely theoretical. The other, by Irène Curie and F. Joliot, is an account of the neutron experiments, particularly those done by the workers in Paris; it contains an interesting set of reproductions of Wilson cloud trails, which supplement those recently published by Feather and Dee in the *Proceedings of the Royal Society*. Each article occupies a little more than twenty pages, and although attractively presented, is certainly cheap.

Cadastral Survey and Land Records

DURING the Conference of Empire Surveyors held in London last year, there was exhibited at the Science Museum a number of cadastral survey, land registry, and land revenue records. The Royal Geographical Society, at the instance of the Secretary of State for the Colonies, has arranged to house these exhibits, and hopes to make them the nucleus of a permanent reference collection in London. It is expected that the collection will include land laws, regulations, and technical instructions from all parts of the world, and will be representative of progressive advances in cadastral survey and land records in each country. Sir Ernest Dowson and Mr. V. L. O. Sheppard have jointly undertaken the collection, study, and maintenance of the documents.

Oil Fuel for Horticultural Purposes

THE seventeenth annual report (1931) of the Cheshunt Experimental and Research Station contains a short account of a test with an automatic heating installation using oil fuel. A thermostat in the tomato greenhouse controls the action of a crude oil burner which gives heat to a special hot-water heating boiler. The account is quite short and the experiment incomplete, but the results show that an enhanced yield can be expected from the increased night temperature. Moreover, the fungus disease known as tomato leaf mould was kept in check by the higher temperature.

Announcements

THE thirty-sixth autumn fungus foray and annual general meeting of the British Mycological Society will be held at Haslemere, Surrey, on Sept. 19–24. Miss G. Lister will deliver the presidential address, entitled "Field Notes on Mycetozoa", on Sept. 21. Several interesting local excursions have been arranged in connexion with the meeting

THE Society of Biological Chemists (India) has made itself responsible for an interesting pamphlet, "Biochemical and Allied Research in India in 1931", in which in about forty pages Indian biochemical research in different fields is summarised in a series of brief reviews by some six contributors. The papers cited, of which the majority appear to have been published in 1930 and 1931, number no less than 181. These brief summaries are grouped under various sub-headings—for example, enzymes and fermentation, agricultural chemistry, chemistry of nutrition, etc.—and seem to be very concisely done, so that this little pamphlet should be useful to many biochemical workers outside India.

THE Society of Petroleum Geophysicists (America) has issued volume 1 of its *Transactions*, comprising a series of important papers presented by the Society at the annual convention of the American Association of Petroleum Geologists at San Antonio in March 1931. Most, if not all, of these papers have appeared in the *Bulletin* of the Association, but now they are available in a convenient, compact form. The titles are: "Application of Seismography to Geological Problems", by E. McDermott; "Belle Isle Torsion-Balance Survey", by D. C. Barton; "Some Results of Magnetometer Surveys in California", by E. D. Lynton; "Magnetic Disturbance caused by Buried Casing", by W. M. Barret; "Brunton Compass Attachment for Measurement of Horizontal Magnetic Intensity", by J. H. Wilson; "Utilization of Existing Wells in Seismographic Work", by B. McCollum and W. W. La Rue; and an "Analysis of some Torsion-Balance Results in California", by R. H. Miller. The editor is F. H. Lahee, and an introduction has been written by G. H. Westby. The volume can be obtained in England from Messrs. Thomas Murby and Co.

APPLICATIONS are invited for the following appointments, on or before the dates mentioned:—A male junior assistant (chemistry) at the Experimental Station, Porton, near Salisbury (War Department)—The Chief Superintendent, Chemical Defence Research Department, 14 Grosvenor Gardens, S.W.1 (Sept. 12). A chief workshop instructor in the Mechanical Engineering Department, at the Northampton Polytechnic Institute, St. John Street, E.C.1—The Principal (Sept. 15).

Letters to the Editor

[The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, nor to correspond with the writers of, rejected manuscripts intended for this or any other part of NATURE. *No notice is taken of anonymous communications.]*

Photography of Penetrating Corpuscular Radiation

SINCE Skobelzyn [1] discovered the tracks of particles of high energy on photographs taken with a Wilson cloud chamber, this method has been used by him and others in a number of investigations [2] of the nature of penetrating radiation. Such work is laborious, since these tracks occur in only a small fraction of the total number of expansions made. We have found it possible to obtain good photographs of these high energy particles by arranging that the simultaneous discharge of two Geiger-Müller counters due to the passage of one of these particles shall operate the expansion itself. On more than 75 per cent of the photographs so obtained (the fraction depending on the ratio of the number of 'true' to 'accidental' coincidences) are found the tracks of particles of high energy.

Mott Smith and Locher [3] had previously found a correlation between the occurrence of these tracks and the discharge of a tube counter, and recently Johnson, Fleicher, and Street [4] have used the coincidence of the discharges of two counters to operate the flash which illuminates a continuously working cloud chamber.

The chamber we used has a diameter of 13 cm. and has its plane vertical, with one tube counter above and one below, so that any ray which passes straight through both counters will also pass through the illuminated part of the chamber. A magnetic field is applied at right angles to the plane of the chamber. When the cloud chamber has been made ready for use, the arrival of a coincidence is awaited. After an average wait of about two minutes, a coincidence occurs and a relay mechanism starts the expansion.

The tracks have a definite breadth due to the diffusion of the ions during the time between the passage of the ray and the attainment of supersaturation. The chamber was designed so that this time

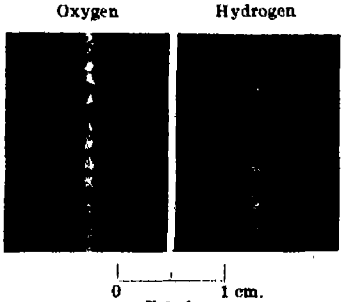

FIG. 1.

should be very small; it was in fact 0·01 sec. The observed breadth of the tracks in oxygen at 1·5 atmospheres pressure was 0·8 mm., and in hydrogen 1·8 mm. (Fig. 1). These breadths are in close agreement with the values calculated from the theoretical relation $\overline{x^2} = 2\,D\,T$, giving the mean square displacement in terms of the diffusion coefficient and the time. In spite of this breadth, the tracks in oxygen are admirably suited for accurate measurement.

The method is very economical in time in comparison with the usual method. Though the track of a fast particle may be obtained every tenth random expansion, only a few of such tracks are of use if an accurate determination of the energy of the particles is to be made. For this purpose it is desirable that a track shall lie in the plane of the chamber, for this ensures that it will be long, in perfect focus, and at right angles to the field. The fraction of random expansions which show such tracks is very small. Again, it is easier to adjust a chamber to take a few good photographs than it is to maintain the adjustment while taking many thousand.

The method has one disadvantage. The technical problem of obtaining a very large magnetic field over the whole chamber, such as has been obtained by

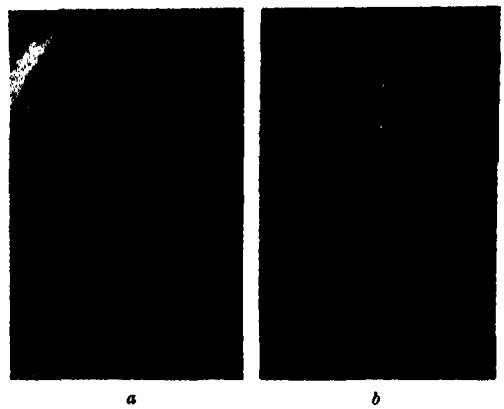

FIG. 2.—Tracks of high-speed particles. (*a*): $H\rho$ about 68,000 gauss cm., corresponding electron energy 20×10^6 volts; (*b*): $H\rho$ probably about 2×10^6 gauss cm., corresponding electron energy 600×10^6 volts.

Millikan and Anderson, is difficult, since the field must be maintained for periods of some minutes, while, when making expansions at random, it is only needed for a fraction of a second.

Among one hundred stereoscopic pairs of photographs, 59 showed the track of a single high speed particle passing through both counters (Fig. 2, *a* and *b*); 17 showed either multiple tracks of varying degrees of complexity, such as have been found by other workers, or else a single track passing through one but not both counters; 24 showed no tracks. Only about ten per cent of the tracks were markedly bent in a field of about 2000 gauss. Assuming them to be electrons, their energies lay between 2 and 20 million volts. To estimate the energy of the particles producing the main group of nearly straight tracks, the angular resolving power of the apparatus was determined by measurement of tracks obtained with no magnetic field. It was found in this way that a *mean* deviation of ½° could be considered as significant. Since the tracks obtained with the magnetic field of 2000 gauss showed no such deviation, it was concluded that the *mean* $H\rho$ of these particles must have been greater than 2×10^6 gauss cm. If the particles were electrons, their *mean* energy must have been greater than 600 million volts, or if protons, greater than 200 million volts.

Intensity of Cosmic Radiation in the High Atmosphere

ON Aug. 12, I succeeded in measuring the intensity of cosmic radiation in the high atmosphere, at air pressures down to 22 mm. of mercury, by means of two rubber balloons and a self-registering electrometer. The electrometer was working on the same principle

FIG. 1.

as that used for the investigations in Lake Constance.[1] The position of an electrometer wire is photographed every four minutes on a fixed photographic plate. The volume of the ionisation chamber was 2·1 litres, the thickness of its walls was 0·5 mm. The air pressure outside and temperature within the apparatus were

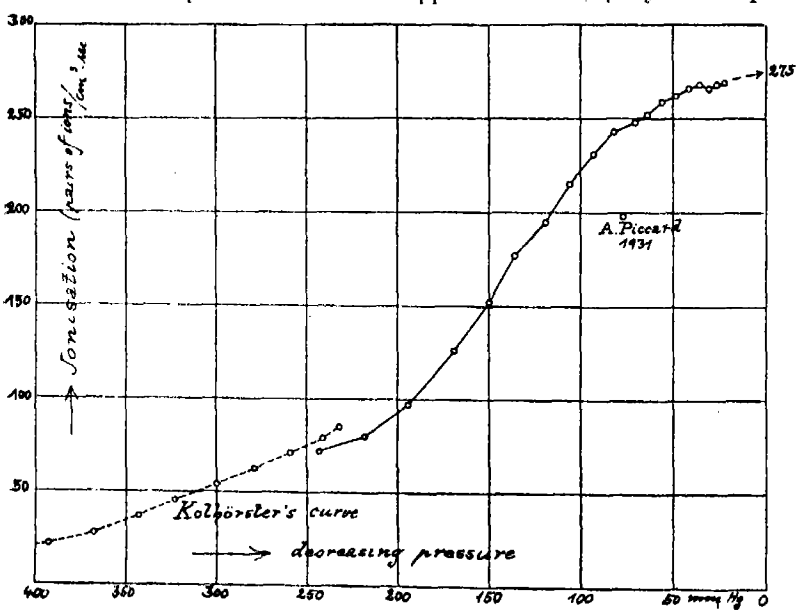

FIG. 2.

measured simultaneously with the electric tension by limiting the length of the wire pictures by an aneroid on one side and by a bimetallic lamella on the other. The apparatus was protected against the low air temperature in the stratosphere by a case of 'Cellophane', which catches the sun's rays like a 'forcing-house'. Therefore the temperature inside the apparatus only varied between + 15° and + 37 C°.

Fig. 1 is a reproduction of the results obtained on the photographic plate. At point 1 the apparatus begins to operate, between points 2 and 3 the tension is measured every 4 minutes, after 3 one of the balloons explodes, point 4 shows the landing. Between 2 and 3 the air pressure (upper limit of the wire photographs) varies from 243 to 22 mm. of mercury.

Fig. 2 shows the results from this plate together with the end of the corresponding curve of Kolhörster and the value obtained by A. Piccard in 1931.[2] The intensity I of the cosmic radiation (I = pairs of ions per cm.^{3} sec.) is given as a function of the decreasing air pressure (in mm. of mercury). The following results may be derived from this curve :

(1) Below 150 mm. mercury (that is, above a height of about 12 km.) the intensity of cosmic radiation increases less rapidly as one approaches the end of the atmosphere.

(2) At lower pressures the intensity approaches rapidly its highest value. Therefore it is possible to extrapolate the intensity of radiation at its entrance in the atmosphere. One gets a preliminary value of 275 I., provided that the intensity does not pass through a maximum value and decrease again at greater heights. This might be the case in consequence of result (3).

(3) The cosmic radiation saturates itself with secondary radiation after having entered the atmosphere. If it remained a mere primary radiation, its intensity would decrease much more rapidly at great heights, and the curve of Fig. 2 would have no point of inflection.

(4) There seems to be no γ-radiation of the common radioactive bodies in outer space. Otherwise it would give rise to a new increase of intensity in the highest parts of the curve, as about 20 per cent of the common γ-rays would pass through a layer of air corresponding to a pressure of 22 mm. of mercury.

Supposing air temperature is constant and equal to 0° C., a height of 28 km. corresponds to a pressure of 22 mm. of mercury.

A more detailed report of the investigation will be published shortly in *Die Naturwissenschaften*.

The α-Rays of Ionium

THE differential method of Lord Rutherford for counting α-particles may of course be used, and with great advantage, for the measurement of the ionisation current. It gives the differential of the ordinary Bragg curve, the variation of the ionisation from element to element of distance, rather than the total ionisation for the element.

I have constructed an apparatus for this purpose capable of considerable accuracy, and the results so far obtained in calibrating it with the α-rays of polonium and ionium have features difficult to interpret. It has three ionisation chambers, 1·85 mm. deep, separated by aluminium leaf equivalent in stopping power to about 1 mm. of air, the one nearest the source being a guard chamber, and the current

through the middle chamber being opposed by that through the posterior chamber. The depth of the latter can be varied by screw adjustment, and, in use, it is set so that the currents balance, with polonium as the source of α-rays, at the beginning of the effective range. The pitch of the screw was $\frac{1}{25}$ in. (1·016 mm.).

The first curves obtained with polonium and ionium are shown in Fig. 1, with the experimental points indicated by circles. Rosenblum has shown by magnetic analysis that the α-rays of polonium are

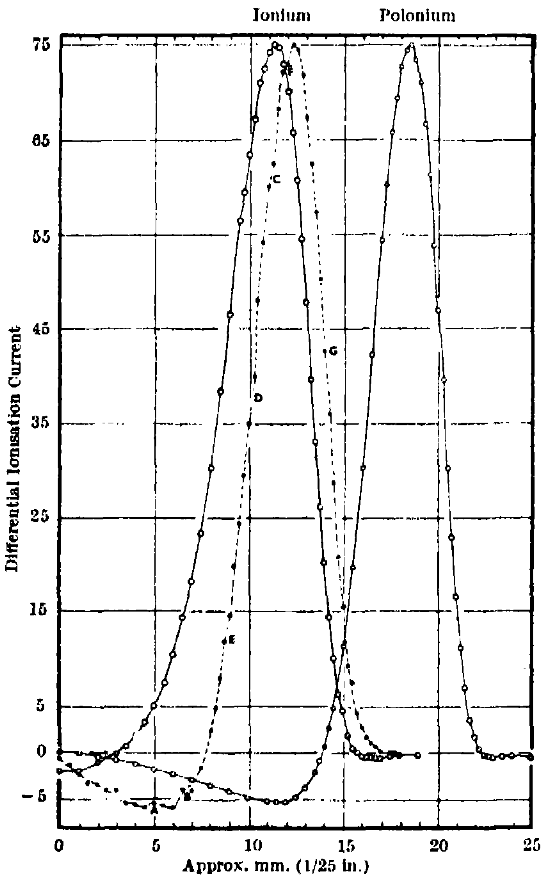

FIG. 1.

homogeneous, and the curve may be taken as that for homogeneous α-particles. It will be seen that on bringing up the preparation from a distance, the current, after rising to a maximum and falling to zero, changes sign and passes through a minimum before reaching zero again at the beginning of the effective range, for which the chambers are balanced. At greater distances, so long as all the rays traverse both chambers, the current in the posterior one predominates, through the increase in ionising power towards the end of the range.

The ionium curve corresponds very closely with that for polonium, so far as the right limb is concerned, but departs markedly for the left limb. The slope is more gradual, and no actual minimum is reached. Also there is a clear inflection at about 2 mm. from the maximum, as though rays of shorter range were present. The ionium employed was an ionium-thorium oxide, prepared by Miss Hitchins and myself from St. Joachimsthal pitchblende residues, and shown, from the rate of growth of radium, to contain ionium and thorium in the ratio 53 : 47.[1] It was finely powdered, and 5 mgm. spread as evenly as possible on a disc 5 cm. in diameter. For a uniform layer, the equivalent stopping power would have been about 1 mm. of air.

To determine the effect due to absorption in the film, another, containing only about 1 mgm. of ionium oxide, was made by evaporating and igniting a solution of the nitrate. Owing to the reduced activity, the curves could not be taken with so great accuracy as before, especially in the neighbourhood of the zero. But all the curves obtained agreed in their main features and differed distinctly from the polonium curve. The mean of the results for the three most complete curves is shown by a dotted line in Fig. 1, the black dots being the experimental points for the most extended single set of measurements.

The minimum is now more pronounced than for the polonium curve and shows definite irregularities at points marked *A* and *B*. The inflection on the left slope in the first curve is marked *C*, and three others are indicated at *D*, *E*, and *F* on this branch, with another at *G* on the right branch. Though small, they appear to be real.

The curves in the figure are not reduced to standard temperature and pressure, but the first two refer to nearly standard conditions. The difference in range between the two ionium preparations is due, one-third to the dotted curve being taken with a lower barometer and higher temperature, and two-thirds to the effect of absorption. Conformably with this, while the corrected ranges found from the two full curves agree with the values usually accepted, 3·87 cm. and 3·195 cm. respectively, the more accurate value for ionium, obtained from the dotted curve, 3·22 cm., is about 0·25 mm. greater than the accepted value.

At first sight it would appear natural to ascribe the irregularities found for the ionium curve to heterogenity of the rays, as found by Rosenblum and others for thorium C, radioactinium and several other 'α-rayers', and to look for a γ-radiation from ionium, which, on Gamow's theory, should be associated with the short range α-rays. I do not think ionium is known to give a γ-radiation, but all my preparations show a detectable penetrating radiation, more penetrating than β-rays, which, though small, is in excess of that due to contained thorium.

Unfortunately, however, for this explanation, the ionium curve obtained for the weaker preparation is distinctly less broad than that for polonium. A careful comparison of the reduced curves showed the latter to be from 0·3 mm. to 0·4 mm. the broader over the lower positive part of the curve. This, owing to straggling, is what is to be expected for the longer range rays of polonium, *if those of ionium are homogeneous*. If the latter were composed of rays of different ranges, this method must reveal it by a corresponding broadening of the curve. The cause of the irregularities thus remains for the present unknown, but more experience with the method may reveal it.

The Glow in Photoelectric Cells

MAKERS of photoelectric cells usually state the limits of e.m.f. which can be used, and beyond which a glow discharge sets in. Although I have not met with any explicit statement, it seems to be implied that short of this e.m.f. no glow is visible.

Recently, when using a 'Madza' thin film cæsium cell (made by the British Thomson-Houston Co., Ltd.)

to indicate the intensity of an infra-red beam, I noticed that the cell was visibly luminous. The luminosity ceased when the infra-red beam was intercepted or the electric circuit broken, and is, without doubt, due to excitation of the residual gas atoms (argon) by electronic collisions. There is, of course, nothing radically new in this, since excitation potentials have been exhaustively studied. The novelty, if any, is that here the source of electrons is a photoelectric surface, instead of the hot wire usually employed.

The older types of photoelectric cells were sensitive only to visible light. This would tend to mask the comparatively feeble glow, and thus prevent its being noticed. In my experiments, the beam was infra-red light, isolated by a filter of red glass combined with a thick block of cobalt blue. The source was a small incandescent lamp focused on the cell, and the residual red passed by the filter was almost imperceptible, making it easy to observe the glow.

Some tests were made to observe the minimum e.m.f. for a perceptible effect. The observer's eyes were well rested in the dark. It was found that when the full working voltage of 70 volts or so was applied, glow filled the whole space between the wire anode and the hemi-cylindrical cathode surface. As the voltage was diminished the luminosity shrank, as might be expected, to the neighbourhood of the central wire, since it is here that most of the voltage is dropped.

Careful experiments showed that luminosity could be seen at 15·85 volts but not at 15·75 volts. These observations were made by my assistant, Mr. R. Thompson, whose eyes are younger than mine. I was not myself able to see light at quite so low a voltage. We may take the intermediate value, 15·8 volts, as the minimum for visible luminosity under the conditions. This is very close to the lower of the two ionisation potentials of argon, which, from the optical evidence, should be 15·72 volts. Luminosity should be observable below the ionisation potential, and, in fact, Horton and Davies [1] were able to observe it at 15·1 volts, using the ordinary hot wire source of electrons.

It has seemed worth while to describe this method of observing with the photoelectric cell, because it is easy and instructive, and requires only ready-made commercial apparatus. If a fairly sensitive galvanometer is included in the circuit, the current–e.m.f. relation can be examined at the same time, and it can be seen that luminosity sets in at about the point where ionisation by collision appears.

The method could perhaps be developed for accurate determination of excitation potentials of the various spectrum lines.

Influence of Light on the Gorging of *Culex pipiens* L.

IN England the blood-feeding habits of *Culex pipiens* have been subject to doubt. Thus, MacGregor [1] states that "Attention must be drawn to the discrepancies which seem to exist between the habits of the representatives of this species in Britain, the U.S.A., France and elsewhere. For instance, great difficulty is ordinarily experienced in Britain in getting *C.* (*C.*) *pipiens* to 'bite' naturally; so much is this the case that it is even now not generally recognised that the species is a blood feeder in this country." Woodcock, on the other hand, says that "*Culex pipiens* is essentially the British mosquito which likes Avian blood".[2] Hitherto the difficulty of inducing *C. pipiens* to gorge under experimental conditions has been a source of difficulty to workers, and MacGregor [3] says that in his work on avian malaria "an unforeseen difficulty arose in that only a very small proportion of the mosquitoes (*Anopheles maculipennis*, *Culex pipiens* and *Aëdes argenteus*) could be induced to feed on birds".

While breeding *C. pipiens* for work on mosquito infection in avian malaria on behalf of the Medical Research Council, we noticed that light appeared to be an important factor in inducing *C. pipiens* to gorge on canaries. Mosquitoes kept in the dark in a thermostat at 25° C. would seldom gorge, whereas those kept in a glass cage in daylight would gorge readily at dusk. When the cage was illuminated overnight during the winter (with a 60-watt electric bulb), they would gorge, when darkened, at any time during the day. In the summer, prolonged exposure to bright daylight is effective without additional artificial light.

Experiments were then made on the comparative numbers of females which would gorge after having been kept for various periods in darkness and in light. In each experiment all the females were bred from eggs laid the same day.

The experiments were done in a two-compartment cage with glass sides. Each compartment could be darkened completely by sliding shutters. The same number of females were put in each compartment, supplied with water and a slice of apple; and one compartment, *A*, was kept dark, while the other, *B*, was illuminated either by daylight and artificial light or entirely by artificial light. A canary was put into each compartment for about three hours daily after various periods of darkness or light, both compartments being darkened while the birds were in. Any gorged females were then removed and counted.

In one experiment 70 females were put in each compartment. Compartment *B* was illuminated continuously with a 60-watt bulb; while *A* was kept dark for 6 days, and was then illuminated in the same manner as *B*. While compartment *A* was dark, only 2 females gorged, whereas in *B*, which was illuminated, 47 gorged in the same time. Further, after 3 days' illumination, the insects in *A* began to bite, and 48 gorged on the following two days.

In another experiment, 51 females were put in each compartment. Compartment *A* was kept dark for 5 days, during which none gorged; but *B* was illuminated by daylight and artificial light during the same time and 34 gorged. *A* was then illuminated for 8 days and during this time 21 gorged.

In a third experiment with 70 females in each compartment, *A* was kept dark for 7 days, during which 2 gorged; and during the same time 32 gorged in *B*, which was illuminated with daylight and artificial light. *A* was then illuminated for 10 days, and during this time 33 gorged.

The temperature was recorded daily in each compartment, and although it fluctuated about 5° C. with the room temperature, it never varied more than 1° C. between the illuminated and the dark compartments.

We have also observed that the females which gorge after being kept in the dark, if dissected immediately after biting, show more developed ovaries and less fat-body than the females kept in the dark.

Further work on these lines is in progress and will be published in detail elsewhere, but the results already obtained show definitely that, under experimental conditions in England, *Culex pipiens* will gorge readily when placed in the dark after prolonged exposure to light, but if kept continuously in the dark will only rarely gorge. In our experiments, of those kept in the dark, only about 3 per cent gorged, while

after exposure to light 66-90 per cent gorged. To our knowledge, this phenomenon has not previously been observed.

By utilising this method of obtaining large numbers of gorged females, and feeding the larvæ on boiled bakers' yeast, we can breed *Culex pipiens* very successfully under laboratory conditions. About 20 per cent of the egg rafts are fertile, and the mortality from eggs to imagines is not more than 10 per cent. Starting with hibernating females, we have now raised the third generation of imagines, each generation having comprised thousands of individuals.

Bionomics of *Trochus niloticus*, Linn.

I HAVE been greatly interested in Dr. C. Amirthalingam's communication [1] about the breeding of *Trochus niloticus* in the Andaman Sea. My own statements on the breeding of this species in the waters of the Great Barrier Reef were based on work done by Mr. F. W. Moorhouse, at that time a member of the Great Barrier Reef Expedition and now Marine Biologist to the Government of Queensland. This work has recently been published,[2] and in addition to much information about the habits and growth of this animal, Mr. Moorhouse states that it appears "to be a winter-breeder, the season extending from March to July at least, and each animal possesses a protracted spawning period". During this period the surface temperature of the water round about Low Isles where these observations were made ranged from about a maximum of 28° C. in March to a minimum of about 20° C. in July.

Dr. Amirthalingam does not give any temperature figures in his letter, but states that spawning begins in the Andaman Seas in April when the temperature is near the maximum for the year before the outbreak of the south-west monsoon. He will doubtless give full temperature records in his final report, which, with Mr. Moorhouse's paper, should go far towards the full elucidation of the bionomics of *Trochus niloticus*, information urgently required in view of the great economic importance of this animal.

Prevention of Blight in Seed Potatoes

IN Jersey, seed potatoes are usually dug when the haulms are green. If blight (*Phytophthora infestans*) is present on the foliage at this time, serious losses may occur in the seed boxes owing to the fungus spores falling on the tubers at digging-time. Losses of fifty to seventy-five per cent are not uncommon.

Experiments carried out at the States Experimental Station, Glenham, have shown that this loss may be almost entirely eliminated by dipping the 'seed' twice, soon after digging, in a 1 per cent dilution of formaldehyde (1 pint of 40 per cent formaldehyde in 99 pints of water) or in a neutral mixture of copper sulphate and caustic soda (4 : 1¼ (about) : 40). Preliminary trials have indicated that dipped and undipped 'seed' sprout equally well.

The method is being tried on a large scale this year. The tubers are dug, placed in the seed boxes, and taken to the farm the same day, where they are dipped before being stored. Four men are able to unload, dip, and stack 360 boxes of seed in one hour.

Sir Richard Threlfall and Sir Horace Darwin

MANY of us have read with much interest the understanding obituaries of Sir Richard Threlfall that appeared in NATURE of Aug. 13. Both obituaries dwell on his inventiveness and powers of work. When looking through some old papers to-day, I found a letter from Sir Richard to his friend the late Sir Horace Darwin. In the course of a conversation on a continuous gas calorimeter, which must have taken place about 1900, Darwin suggested that it was advisable to link up automatically the quantity of water heated by the gas flame with the quantity of gas burnt. Threlfall did this, and obtained a recording calorimeter which was far in advance of any other instrument for many years. The letter was evidently written by Threlfall to Darwin after one of the concentrated periods of work referred to in the first obituary notice. It was accompanied by a clear sketch and notes in Threlfall's handwriting.

"Birmingham,
April 7th, 1903.

MY DEAR DARWIN,

Let it be granted that I am an ass—this will prevent your being able to claim to have discovered it after reading the rest of the letter. I have been looking out for more than a year for a neat mechanism to replace that hydraulic gear I use with my instruments, but I never really tried at it till last Sunday, and I was lucky enough to get a very simple device. I think it might work in with some of your things, the recorder, *e.g.*, so I will tell you about it, please regard it as a sort of exchange (a poor one I know) for your hints on the gas meter. The problem was:

Given one clock, and the power of making two electric contacts: to operate a shaft by the clock in either direction of rotation, to lock the clock when neither contact is made. Also the magnets worked by the contacts must not require too much current; the inertia of everything must be small so as to start and stop quickly.

I hope you may find the thing of use—I never knew a simple device which had all the advantages at once and consistently—before.

Yours very truly,
R. THRELFALL."

The sketch and notes were made by a man who was a mechanic, and were sent to one whom Threlfall knew would appreciate and approve of small but important points in design.

I think it will be agreed that the letter shows a delightful spirit of friendship between the two distinguished inventors.

A Possible Connexion between the Troposphere and the Kennelly-Heaviside Layer

SEVERAL experimenters have noticed the existence of a correlation between alterations in the propagation of radio waves and the establishment of certain meteorological situations: but, until now, no definite result could be obtained. I have therefore investigated directly the relation of the Heaviside layer, on which the propagation of radio waves depends, to meteorological conditions.

From May 1931 until June 1932, I made, at short intervals, daily observations on the reflection height of waves of 100 metres in wave-length by means of a device invented by me some time ago.[1] The waves of 100 metres wave-length, as is well known, are generally reflected in the E region during daylight, and generally from some time just before or after sunset until sunrise their reflection takes place in the F region.

The time near sunset when the reflection is passing from the E region into the F region often presents remarkable variations from one day to another: the reflection from the E layer sometimes continues for a long time after sunset, until midnight even, for waves of 70-50 metres wave-length; at other times, after disappearing by sunset, reflection appears again a few hours after sunset itself. This is evidence of the existence of remarkable increases of ionic density in the E region, even after the action of ionising solar radiations has ceased. The examination of the data which were obtained from about 330 days' observations has led to the following conclusions:

The abnormal increases of ionic density in the E region are accompanied by particular isobaric situations, characterised by the presence of barometrical depressions at the place of observation or in the north of it. In anticyclonic conditions, or conditions with depressions in the south, the reflection of 100 m. waves from the E region ceases in the shortest time; from noon onwards ionic density gets rapidly smaller. In 330 days' observations I found only some ten exceptions to the above general rules.

The existence of a connexion between the troposphere and the first ionised layer (E) is therefore clearly suggested; its nature will be the subject of future investigations.

An Optically Active Inorganic Salt

IN 1914. Werner[1] described the resolution into optically active forms of dodecammine-hexol-tetracobaltic hexabromide, $[Co[(HO)_2Co(NH_3)_4]_3]Br_6$. This has remained until recently the only example of an inorganic (that is, carbon-free) salt the molecular dissymmetry of which has been proved by optical resolution. A second optically active inorganic salt, which, although also of the 'complex' type, is of much simpler composition than Werner's salt, has now been obtained.

Sulphamide, $H_2NSO_2NH_2$, has long been known to act as a weak dibasic acid. When certain rhodium salts are treated with sulphamide dissolved in sodium carbonate solution, co-ordination occurs with the formation of sodium di-aquo-rhodium-disulphamide, $Na[(H_2O)_2Rh(HNSO_2NH)_2]$, a compound of the 'diammino-tetracido' type in which each sulphamide residue occupies two co-ordinate positions. This salt should be capable of existence in two isomeric forms, one having the two water molecules in the 1 : 2 or *cis* positions in the six-co-ordination octahedron, and the other having these molecules in the 1 : 6 or *trans* positions. The first isomeride is dissymmetric, and should be resolvable into optically active forms, whilst the second possesses a plane of symmetry and should be non-resolvable.

When an aqueous solution of this sodium salt was treated with *dextro*-nor-ψ-ephedrine sulphate, the alkaloid salt of the complex anion was slowly precipitated; the first fraction thus obtained, on treatment with sodium hydroxide, gave a *lævo*-rotatory sodium salt having, for the mercury yellow line, $[\alpha] = -9 \cdot 6°$ and $[M] = -34°$. Treatment of the racemic sodium salt similarly with *dextro*-phenyl-ethylamine hydrochloride gave the amine salt, which in turn furnished a dextro-rotatory sodium salt having $[\alpha] = +8 \cdot 9°$ and $[M] = +31°$. Although it is not claimed that these represent the optically pure enantiomorphs, the resolution proves the presence of the 1 : 2 or *cis* isomeride in the sodium diaquo-rhodium-disulphamide.

Platinum compounds of similar composition have also been prepared, and their resolution is now being investigated.

Dimensions of Fundamental Units

THE recent world-wide discussions upon the electrical and magnetic units and their dimensions have focused attention once more upon the discrepancies which occur in the various textbooks. It has always seemed to me that there was no justification for regarding the three magnitudes, mass, length, and time, as necessarily fundamental, and a system in which quantities expressed in those dimensions have fractional indices is unsatisfactory. If we take the course of regarding quantity of electricity as a fundamental, and introduce Q for its dimension, we get the following table:

Quantity.	Dimension.
Quantity	Q.
Current	$Q.T^{-1}$.
Magnetising force	$Q.T^{-1}.L^{-1}$.
Magnetomotive force	$Q.T^{-1}$.
Magnetic Flux	$M.L^2.Q^{-1}.T^{-1}$.
Flux density	$M.Q^{-1}.T^{-1}$.
Permeability (μ)	$M.L.Q^{-2}$.
E.M.F.	$M.L^2.Q^{-1}.T^{-2}$.
Resistance	$M.L^2.Q^{-2}.T^{-1}$.
Sp. Ind. Capacity	$Q^2.T^2.M^{-1}.L^{-3}$.
Pole strength	$M.L^2.Q^{-1}.T^{-1}$.

It will be noticed that the introduction of a new dimension has automatically wiped out all fractional indices; but this is not all. Examination of the dimensions shows that wherever Q appears in the numerator, M appears in the denominator and vice versa. Consequently, if M be regarded as a function of Q, the former would disappear entirely from the table, and everything in mechanics, as well as in electricity and magnetism, could be put in terms of Q, L, and T.

Further, on the assumption that magnetism is due to spinning electrons, we obtain for μ the expression $\mu = \tau eh/4\pi m$, where τ is a pure number. Here again, then, on the above assumption, Q and M will cancel.

It seems to me that these simplifications are too striking to be merely a matter of coincidence.

Research Items

The Towednack Gold Hoard.—The affinities and dating of the hoard of gold objects found at Towednack, Cornwall, in December 1931 and May 1932 (see NATURE for Jan. 16, 1932, p. 90) are discussed in *Man* for August by Mr. Christopher Hawkes. Nine pieces were found, of which four are finished ornaments, two torcs, and a pair of bracelets. Two bracelets are unfinished and the remaining three pieces are bent rods or bars, evidently a goldsmith's raw material. No. 1 is a large torc, 45 inches in length, with enlarged terminals, circular in section, tapering inwards. The main portion is triangular in section and twisted from right to left. The whole is coiled double, and the terminals twisted for interlocking. No. 2 is a triple torc of a pattern hitherto unknown in prehistoric gold work, the body of the torc being formed of three strands of gold wire, each of triangular section and twisted like No. 1. The strands are welded together at the ends to form the terminals, which are bent back to interlock. It measures 4-4½ inches across. Nos. 3 and 4 are a pair of bracelets, quite plain, formed of rods circular in section, bent in an oval penannular form. They are excellently finished, smoothed, and polished. Nos. 5 and 6 are obviously unfinished, awaiting smoothing and polishing, but clearly intended to be quite plain like the previous pair. Of the rods, one is lozenge-shaped in section, the others irregular. There is no reason to think the gold is not of Wicklow origin. The two torcs obviously provide the firmest basis for chronology, and although the second is without parallel, its complexity of structure and fineness of workmanship point to an advanced stage in the development of torc manufacture. The simpler workmanship of No. 1 invites an abundance of comparative material, and an examination in detail of torc types suggests that it is a developed type, but earlier than the fully established Late Bronze Age types, for example, the Morvah hoard, and preceding the full establishment of the Late Bronze Age culture in Cornwall and Ireland. It belongs, then, to the period 1000–750 B.C., a period of transition, perhaps marking a renewal in the Irish-Cornish gold and tin trade.

Menominee Indian Music.—In a report on an investigation of the music and song of the Menominee Indians of Wisconsin (*Bull.* 102, Bureau of American Ethnology), Miss Frances Densmore records a close resemblance in ceremony and custom, as well as in the songs accompanying them, to the Chippewa. The medicine lodge of the Menominee is practically identical with the Grand Medicine Society of the Chippewa; and in the drum ceremony, which originated with the Sioux and is thought to contain elements of Christianity, the observances of the Menominee are closely akin to those of the Chippewa. On the other hand, in the use of war-bundles and hunting-bundles and in the morning star legend, they resemble the Winnebago. The songs recorded are mostly of a ritual character; but there are also love songs and lullabies. Some of the songs are those used in connexion with the ritual games, the bowl-and-disc game, the double-ball game, and lacrosse, which are played ceremonially for the benefit of a person who has dreamed a dream. The ceremonial character of the game is indicated by the fact that it is immaterial which side wins. Songs sung in connexion with adoption dances are recorded, as well as a number connected with treatment of the sick. Underwater and underground powers are frequently mentioned in connexion with the songs. Chief among the latter is the 'underground bear', a white bear larger than a grizzly, said to be an ancestor of the Menominee tribe. It emerged from the ground as an Indian near the present site of Marinette, Wis., and was followed by more Indians. The chief of the 'underwater' powers is the 'underwater snake', usually referred to as the 'hairy snake', which lives in the water and personifies the powers of evil. If the body of anyone who has been drowned is found in an upright position, it is believed that he has been drawn down to his death by the underwater snake.

The Arthrodira.—Of recent years there has been a considerable accession to our knowledge of the Arthrodira. This group of Devonian fish-like animals has had a chequered career in regard to its zoological position. At first regarded as water beetles, these animals next became reptiles, and at length were recognised as fishes of some kind. Recently, Stensiö in an important paper on the head of *Macropetalichthys*, in which a very detailed account of the elasmobranch-like brain structure is given, came to the conclusion that the Arthrodira as a whole were true fishes and represented an early offshoot of the elasmobranch line. The most recent pronouncement on the subject is by Heintz (Anatol Heintz, "The Bashford Dean Memorial Volume", Article 4, 115-224. American Museum of Natural History, 1932). This investigator not only denies the elasmobranch relationship of the Arthrodira, but, while agreeing that *Macropetalichthys* is elasmobranch in affinity, also disputes its connexion with the Arthrodira. If this be the case, then the evidence of the elasmobranch affinity of the Arthrodira, based as it is chiefly on the structure of *Macropetalichthys*, falls to the ground. Heintz returns to an older view that the Arthrodira (together with the Antiarchi) form a separate group unconnected with any other group of fishes, and one which is perhaps not to be considered as formed of true fishes at all. They are ranked therefore as a class equivalent to the classes Agnatha (Cyclostomata) and the Pisces, and the name Placodermata, given by McCoy in 1840, is restored. The chief character on which this view is based appears to be the structure of the jaws, which is *sui generis* and unknown in any other form of animal.

High-Moor Vegetation of Eastern Prussia.—Dr. Reimers and Dr. Hueck have recently given an account of the high-moor vegetation of eastern Prussia (*Abhand. d. Math-naturw. Abt. d. Bayer Akad. d. Wiss.* Suppl.—Band 10 Abh. Munchen 1929, pp. 407-494, 12 plates, 2 maps, and 14 text figures). This is of an extensive rather than intensive character, based on the examination of a number of examples for which species lists are furnished and relative frequencies given. Most of the moorland communities described appear to conform in general terms with the zonal communities presented in the moorland of Ezeretis. Here open water occupied by *Nymphæa* and *Nuphar* is succeeded by a community in which the dominants are *Carex limosa–Scheuzeria palustris* and *Oxycoccus vulgaris*. The last-named is also common in the next zone dominated by *Rhynchospora alba*. A drier community is characterised by *Andromeda polifolia–Drosera anglica* and *Sphagnum rubellum* (in contrast to *S. cuspidatum* in the preceding zones). The driest area is occupied by *Calluna* heath, which in its damper parts is associated with *Ledum palustre* and *Rubus chamæmorus*, whilst in its drier parts colonisation by *Pinus sylvestris* may take place. Low moor vegetation also occurs locally with *Menyanthes trifoliata, Ranunculus lingua, Peucedanum palustre, Comarum palustre, Aspidium thelypteris*, etc. A number of transition types are described; also several woodland communities, the status of which is not quite clear.

Inheritance of Resistance to Wilt Disease in Cotton.—An investigation of the resistance of Egyptian cotton to the wilt disease (*Fusarium vasinfectum*), and its inheritance, has been made by Dr. Towfik Fahmy (*Bull.* No. 95, Ministry of Agriculture, Egypt). He classifies plants as susceptible, resistant, or immune according to whether they die as seedlings in infected soil, recover after developing mottled leaves, or show no symptoms. Some Egyptian varieties are completely susceptible, while others show a percentage of resistance and immunity. In crosses, immunity is dominant to susceptibility. The F_2 in one cross (Giza 7 × Sakha 3) gave 75 per cent immune, 15 per cent resistant, and 10 per cent susceptible. The immunes may segregate or breed true. The resistant plants in F_3 may give all three types or only immune and resistant. In a cross between susceptible and immune, there is an increase in the resistance of susceptible plants, as measured by the incubation period before the symptoms of the disease appear. Also, mother plants with a long incubation period have a higher percentage of immune progeny than those with a shorter incubation period, which are therefore less resistant. The correlation between susceptibility and length of fibre has also been studied.

Slime Moulds in Soil.—"The Distribution of Dictyostelium and other Slime Moulds in Soil" (K. B. Raper and Chas. Thom. *J. Wash. Acad. Sci.*, **5**, 22, No. 4, pp. 92-96, 1932) describes the occurrence in soil of various members of the Acrasieæ, a group of fungi closely related to the Myxomycetes, but which reproduce by means of amœbæ and have no flagellate stage. The organisms described belong to the genera *Dictyostelium* and *Polysphondylium*, and have hitherto been regarded as manure-inhabiting fungi. The present report shows that they are a normal part of the soil micro-flora, and clears up one of the puzzles as to the identity of the amœboid forms found in soil. The use of suitable culture methods will probably show that many of the so-called amœbæ in soil are only stages in the life-histories of such fungi.

Geology of Uganda.—The Annual Report of the Geological Survey Department of Uganda for 1931 (Entebbe, 1932, pp. 20) records many features of geological interest. Mr. W. C. Simmons has discovered a true unconformable sedimentary junction between the Karagwe-Ankolean beds and the underlying basement complex. Dr. A. W. Groves has proved the existence in Uganda of a charnockite series closely paralleling that of India. As in India, some of the occurrences are associated with magmatic iron ores and graphitic schists. The chromium-bearing mica, fuchsite, has also been found in the charnockite areas. Dr. Groves records the effects of shearing movements on the crystalline rocks on both sides of Lake Albert. He finds that the degree of brecciation, granulitisation, and mylonitisation is related to the distance of each specimen from the nearest rift scarp, and reaches the conclusion that the disturbances bringing about the formation of the Albertine rift valley were responsible for these shearing effects. The observations thus support the compression hypothesis of rift-valley formation. They also imply the removal of a considerable overburden by denudation, corresponding to the accumulation of thick deposits in the Albertine depression. The tectonic activity which gave rise to the rift, and is probably still in progress, must therefore have begun long ago. It is announced that Mr. Combe has completed his memoir on the tinfields of Ankole. The finding of cobalt and nickel-copper ores on Ruwenzori is also recorded.

Distribution of Earthquake-Centres in the Philippines.—Father W. G. Repetti, *S.J.*, who recently studied the distribution of Philippine earthquake-centres north of Manila during the years 1920–29 (see NATURE, **129**, p. 367; 1932), has continued his work on those lying to the south of the capital. During the same ten years, there were in this region 102 earthquakes, the epicentres of which could be determined with accuracy by means of seismographic records. With one exception, all these epicentres were submarine. The most important zone is the ocean trough known as the Philippine Deep lying off the east coast of Mindanao. Epicentres are concentrated in two principal areas, one in lat. 6° 30′ N., long. 126° 40′ E., the other in about lat. 7° 45′ N., long. 127° 10′ E., both lying between 25 and 30 miles east of Mindanao.

Gas Burner Design.—The Bureau of Standards at Washington, in co-operation with the American Gas Association, has been engaged for some time determining the conditions which limit the efficient operation of gas burners of various types using gases of many different compositions, and the results so far obtained are embodied in a paper by Messrs. J. H. Eiseman, E. R. Weaver, and F. A. Smith in the June issue of the *Journal of Research*. In it the conditions which were indicated qualitatively in Circular No. 394 of the Bureau are specified quantitatively for a domestic burner of the 8-prong star type with 44 jets. For each rate of supply of gas measured in British thermal units per hour per jet, the percentage of the total air necessary for complete combustion which must be mixed with the gas before it arrives at the jet, and which on one hand will prevent a yellow tip and on the other neither produce a flash back nor a blow out, is shown by curves for jets of various diameters. The influences of the height above the jets of the utensil to be heated on the production of carbon monoxide and on the efficiency of the burner are also shown.

Crystalline Structures in Glasses.—Lord Rayleigh has published a set of photographs of various glasses, taken between polarising nicols, which show the presence of particles and threads, in size very approximately of the order of a millimetre, having crystalline structure not due to mechanical strain (*Proc. Roy. Soc.*, July). These had been previously found in fused quartz and a phosphate glass known as Corex, and were likened to the Lehmann structure in liquid crystals. They are not present in silica glasses which have not a large silica content, the limiting quantity being about 80 per cent, as in Pyrex. Silica is also not essential for their production, as they may appear in phosphate and borate glasses. When present, they naturally make the material incompletely isotropic, and their complete removal presents an interesting, if not indeed an intractable problem. The effect is possibly connected with the devitrification of glasses and the crystal structure found in them by means of X-rays.

Protein Monolayers.—Investigations of proteins as monomolecular films on liquids, a method previously attempted with indifferent success, has now been developed satisfactorily by E. K. Rideal and A. H. Hughes (*Proc. Roy. Soc.*, July). In the earlier work, the films formed were probably not homogeneous; in the present work, homogeneous films of known weight have been made by depositing a fragment of the protein from the tip of a delicate quartz fibre microbalance. These films were then examined by compressing them on the surface in a Langmuir film apparatus, as well as electrically and optically. Gliadin, with which most of the work was done, gave homogeneous films with a thickness so low as 3 A., which changed on compression to a form having many of the properties of a gel, and quite possibly

the two-dimensional analogue of this state of aggregation. It is supposed that the basic polypeptide chains of the protein are stretched out flat on the surface in the most expanded state of the film, and that on compression and gelation the side chains to the main polypeptide chain are forced out of the surface.

The Heavy Hydrogen Isotope.—Of several recent papers on H^2, one by E. W. Washburn and H. C. Urey (*Proc. U.S. Nat. Acad. Sci.*, July) is of outstanding importance in indicating a possible electrochemical method for separating it in quantity. In electrolysis, there will probably always be some difference between the electrode properties of different isotopes of the same element. Generally, this will be small, but with hydrogen it is apparently significant, and in the electrolysis of water the residual liquor should perhaps contain a marked excess of the heavy isotope. A long experiment to test this is in progress at the United States Bureau of Standards, but meanwhile some commercial residues have been examined, and show the expected enrichment qualitatively. Other chemical reactions might produce a similar change in the relative amounts of H^2 and H^1, and the problem of their relative abundance in Nature is thus complicated by the history of the hydrogen-containing substances investigated. In the first July number of the *Physical Review*, the concentration of H^2 in 'ordinary' hydrogen is estimated to be about 1 in 30,000 by W. E. Bleakney, from mass-spectrum measurements, and the mass of H^2 is given as $2 \cdot 01353 \pm 0 \cdot 000064$ by K. T. Bainbridge; no evidence for the presence of helium isotopes could be found by the former.

Colour and Mineral Content of Honey.—Analyses of several specimens of American honey by Schuette and Remy (*J. Amer. Chem. Soc.*, July), in which special attention was given to the presence of manganese and copper, on which emphasis has been laid by students of nutrition, have given interesting results. The analyses of twenty-two specimens of honey, of which eighteen were taken directly from the comb, showed that the mineral content of the dark-coloured varieties was higher than that of the light-coloured. The manganese and copper contents were also higher in the darker-coloured honey. The average percentage of ash in the light honeys was 0·06, that in the dark honeys 0·17. The light honeys contained an average of 0·29 mgm. copper and 0·30 mgm. manganese, the corresponding values for the dark honeys being 0·56 mgm. and 4·09 mgm. The maximum figures were 0·70 mgm. copper and 0·44 mgm. manganese for light honeys, and 1·04 mgm. copper and 9·53 mgm. manganese for dark honeys. The characteristics and flavour of honey are probably influenced to a marked degree by nectar and pollen. They, in turn, may well vary in composition and quality according as the plant which produced them is affected by such growth factors as the meteorological conditions prevailing in its habitat and the nature and fertility of the soil. It is suggested that a dark honey should have a higher nutritive value than a light one, although colour and quality often bear an inverse relationship to each other in the lay mind.

Astronomical Topics

The Corona without an Eclipse.—*L'Astronomie* for June contains an article by M. B. Lyot, giving further particulars about his results obtained at the Pic du Midi. He states that the brightness of the inner corona is about equal to that of the planet Mars, which is readily visible in daylight; but observation of the corona is rendered more difficult by the great brightness of the sky near the sun; this is, however, greatly diminished at a height of 10,000 feet, especially when cloud and dust are absent; a further difficulty, due to diffused light in the telescope, is diminished by keeping the lenses quite free from dust, and by placing diaphragms in the tube, slightly larger than the solar image, to shut off sunlight. In order to distinguish instrumental defects from genuine solar markings, the coronagraph was rotated slightly between exposures; instrumental markings remain in the same place on the plate, but solar ones follow the solar image. Using a red screen, it was possible to view prominences directly, without a spectroscope; a Wratten screen, transmitting light between wave-lengths 6500 and 6600, permitted photographs to be taken of coronal jets, rising to a height of 7′ above the sun's limb.

M. Lyot gives measures of the wave-lengths of the green and red lines in the coronal spectrum; the plates were measured at Meudon by M. H. Grenat, who found for the green line 5302·83 on the east of the sun and 5302·87 on the west; the difference is in the right direction for rotation, but no stress is laid on this. The line in the red, which was traced to a height of 6′ above the limb, gave wave-length 6374·75, but with a probable error of 0·15. Unsuccessful attempts were made to photograph other lines at 4232, 4086, and 3986, which had been obtained from eclipse photographs.

M. Lyot notes, in conclusion, that sunspot activity was decidedly low when these results were obtained; he hopes for better results near maximum. He makes the observation that much longer exposures can be given than during eclipse.

Sunspots and Comet Activity.—De Morgan in his "Budget of Paradoxes" describes as a joke a correspondence between Pons and von Zach, in which the latter humorously explained Pons's failure to find comets during a certain period by noting that sunspots had also been absent then; Pons took this seriously and made a successful search for a comet after the return of large sunspots. De Morgan adds, "It would mend the story exceedingly if some day a real relation should be established between comets and solar Spots". Something like this suggestion has now actually come to pass. *Popular Astronomy* for May contains an abstract of a paper by Messrs. Hulbert and Maris, which brings forward many striking instances in which unusual solar activity has synchronised with remarkable phenomena in comets visible at the time. It is not the first time that the suggestion has been made. It was noted that the activity of Morehouse's comet in September 1908 came at a time of spot activity; the greatest magnetic storm of the year occurred on Sept. 11; many people thought then that the two events were connected. Indeed, since all cometary activity is now ascribed, directly or indirectly, to solar action, it is quite to be expected that the action of the sun on comets should depend on its state of activity.

Hulbert and Maris note that there were magnetic storms in the autumn of 1835, when Halley's comet exhibited striking changes, and again that a great storm occurred on Dec. 3, 1846, a few days before Biela's comet split in two. Of course, the solar activity does not bring comets, but it may well increase the brightness of those that happen to be there, and so increase the chance of discovery. It thus appears that the jest of von Zach may be taken in earnest.

The Solar Chromosphere *

THE spectrum of the solar chromosphere may be observed at a time of total eclipse by various methods. Frequently the thin crescent of the solar gases is photographed through a prismatic camera, the crescent itself acting as slit. In 1898, Dr. W. W. Campbell devised an important modification of this method of observing the flash spectrum. It consisted in the introduction of two new features, (1) a wide slit in the focal plane of the camera perpendicular to the dispersion and so to the monochromatic image-crescents, (2) a moving photographic plate moved during the exposure in its own plane in a direction perpendicular to the slit. The slit permits a short length (of the order of $\frac{1}{32}$-inch) of the central portion of each crescent to fall on the plate.

In the resulting photograph each bright line in the usual flash spectrum appears as a longer or shorter bright line, straight and normal to the dispersion, terminating at one end at a point corresponding to the instant at which the whole radiation from the still uncovered chromosphere is insufficient to affect the plate. In the other direction each bright line ultimately 'fades' into the corresponding Fraunhofer absorption line.

The intenser the radiation from the chromosphere for a given distribution of intensity with height, the longer the line outside the apparent limb-level; and similarly the less rapidly the intensity decreases with height, the longer the line. The apparent limb-level is well marked in the photographs, and it is possible to analyse the spectrum from the moving-plate spectrogram at any assigned 'height' on the plate, but it must be remembered that the 'intensity' at any given 'height' on the plate is a function not of the chromospheric radiation at that height but of the integrated chromospheric radiation for all levels above that height. Thus the spectrograms are not what they appear to be at first sight, and some mental effort is required to keep the true interpretation vividly in mind.

The method was successfully employed by Campbell at the eclipses of 1898, 1900, 1905, 1908. Though these results were described in brief immediately after each eclipse, full details waited until the present. We now have, in this splendid volume from the Lick Observatory, the complete analysis of the chromosphere results by the moving-plate method and a series of reproductions of the spectrograms. The work has been carried out by Dr. Donald H. Menzel, and he is to be congratulated on the service he has rendered to solar physics.

In the introduction, Dr. Campbell defends the moving-plate method against criticism, and points out its advantages as a *continuous* record of the changes in the flash spectrum as the chromosphere is gradually covered or uncovered by the moon. Approximately two-thirds of the volume is occupied by spectroscopic tables, computed by Menzel. These tables give possibly the most complete information on the flash-spectrum yet published. The whole of the measures are arranged twice over, once according to wave-length and then again arranged according to element, the full multiplet designation being given for each line, together with estimates of its 'intensity' at various 'heights' as measured by microphotometer tracings. The labour of compilation must have been immense, and the double tabulation will enormously smooth the paths for future workers.

Dr. Menzel reaches the surprising conclusion that the contours of all chromospheric lines at any given level are essentially the same curve, the vertical scale only being different; and further, that the contours are broader and more flattened at the higher levels. As Menzel says, this is the reverse of what would be expected. Insufficient information is given about the apparatus employed, etc., to form a judgment whether the effect is real or simply a photographic effect. The reproduction of a few microphotometer tracings would have been of interest.

The remaining one-third of the volume is a valuable digest of current theories of contours of spectral lines in stellar atmospheres, degrees of ionisation, etc., together with various applications to the results of the chromospheric observations. It is extremely useful to have a consistent treatment of the whole problem; and Dr. Menzel's analysis is in many places original. His final conclusion (stated with critical reservations) is that the chromosphere is probably in a state of turbulence in which radiation pressure plays a part. He criticises the attribution to the chromosphere of a static form of equilibrium under radiation pressure, but it may be noted that he ultimately shows (p. 286) that Minnaert's observed value of the residual central intensity in the ionised calcium lines is consistent with an almost 'fully-supported' chromosphere. Dr. Menzel's analysis is throughout directed towards an attempt to infer what is the actual state of the chromosphere as implied by observation; he is not in general concerned with the more fundamental problem of why the chromosphere comes to have its particular state. Some of the theories of chromospheric equilibrium which he views unfavourably owed their origin to an attempt to see in what ways it is possible for a stellar atmosphere to thin out into space, how radiation pressure rises into importance as collisions become rarer, and similar problems, rather than to impose a particular theoretical constitution on the solar layers. But Dr. Menzel's whole outlook is stimulating, and his volume will be a rich treasure-house, of both observation and theory, to all future workers on the subject.

Part 1: A Study of the Solar Chromosphere based upon the *Photographs of the Flash Spectrum* taken by Dr. William Wallace Campbell, Director of the Lick Observatory, at the Total Eclipses of the Sun in 1898, 1900, 1905 and 1908, by Donald H. Menzel. Pp. v + vi + 303 + 9 plates. (Berkeley, Calif.: University of California Press, 1931.)

Resuscitation in Asphyxia

THE recovery of persons in whom breathing has ceased following the inhalation of water or a noxious gas is attempted by artificial respiration, the method most generally adopted being the Schäfer prone pressure method. In certain cases, however, this method may not be suitable, or it may be inadequate to restore the normal respiratory movements. In collapse on the operating table under an anæsthetic, the cessation of breathing is sometimes quickly followed by stoppage of the heart: recovery may follow artificial respiration alone, or after cardiac massage or the injection of adrenaline into the heart in addition.

An experimental basis for the use of adrenaline is given by the results obtained in a recent investigation by Sir E. Sharpey-Schafer and W. A. Bain (*Proc. Roy. Soc. Edin.*, vol. 52, p. 139; 1932). Cats anæsthetised

with urethane were asphyxiated by occlusion of the trachea: the respirations became slower, and later deeper as well, and finally ceased: about a minute later a series of gasps occurred, which were usually ineffective in restoring the circulation (the trachea having been opened) unless the heart was also beating. The blood pressure fell when respiration ceased, and the heart gradually stopped.

Manual pressure on the chest may now cause recovery, both by renewing the air in the lungs and by pumping blood through the heart; artificial ventilation of the lungs alone may fail. The blood pressure may rapidly rise to an abnormal height before settling to the normal level, probably due to passage of adrenaline in the stagnant venous blood through the heart and arteries. The injection of adrenaline into the heart, especially the myocardium, will restore the beat to normal if the organ is beating feebly, or will arouse it again if given fairly soon after stoppage, together with inflation of the lungs. At the same time, it constricts the arteries and raises the blood pressure to its normal level or even higher. With restoration of the circulation, the breathing also returns, and though at first slow and deep, gradually becomes normal in character and rate. The injection of adrenaline into the heart, together with artificial respiration, will only be successful in the human being provided the breathing and circulation have not been too long in abeyance; ten minutes is probably the limit in ordinary circumstances.

The manual method of artificial respiration is inconvenient and difficult to apply successfully over a prolonged period of time; P. Drinker and L. A. Shaw have invented a mechanical respirator for use in the respiratory paralysis of anterior poliomyelitis in children and in cases of respiratory failure due to carbon monoxide poisoning, electrocution, drowning, etc. (*J. Franklin Inst.*, vol. 213, p. 355; 1932). The patient is placed, except for his head, in a closed chamber; the neck is encircled by an air-tight flexible rubber collar. Air is rhythmically pumped from the chamber, producing inhalation in the patient; exhalation occurs when the air pressure returns to normal. The patient's respiration is completely under the control of the machine when the negative pressure is 7 cm. of water. The apparatus has been found so successful that more than 150 are now in use in the United States and Canada. It is of interest to note that the optimum diameters of the rubber collar and head hole in the lid were obtained by plotting frequency curves from manufacturers' sales of different sizes of collars and hats.

Cosmic Radiation

IN a paper presented at the recent International Electrical Congress held at Paris, Prof. R. A. Millikan summarised in a convincing manner his views concerning the nature and origin of the penetrating cosmic radiation. The idea that they are neutrons, although it would combine the advantages of particles with failure to be deflected in the magnetic field of the earth, he considers unnecessary and not superior to the photon hypothesis. Commenting on the experiments which have been made to find if there is any preferential direction in which they enter the air, Prof. Millikan takes the view that there is no evidence that they are other than isotropic; this is in accord with his interpretation of their absorption curve, according to which the cosmic rays arise from processes involving the agglomeration of hydrogen nuclei for, probably, a very long time until they condense catastrophically to form a new nuclear type, which could scarcely occur where the temperature and pressure were not extremely low, as in interstellar space.

This paper contains some details of the experiments which have been made by Anderson in the Norman Bridge Laboratory in California, with a Wilson expansion chamber. The main aim of these was to deflect the products of the interaction of the rays with matter in a magnetic field, but many interesting subsidiary observations have been made.

The cosmic rays appear to be absorbed largely by nuclei, in general accord with the supposition that they arise in nuclear processes, but destroying the validity of the immediate application of the Klein-Nishina absorption formula, which assumes interaction with the extra-nuclear electrons. About thirty good trails have been photographed. Eleven show a proton with an energy of the order of some 10^8 electron-volts, two an electron of similar energy, three protons of between sixteen and forty million volts, five electron trails of about ten million volts, and the remainder particles of greater energy than 5×10^8 volts. The reality of the latter would not be in agreement with Prof. Millikan's atom-building postulates, the energy being excessive, but there is some doubt if they are authentic, as the trails show a number of sudden small deflections which are difficult to reconcile with the transit of such energetic particles. In seventeen per cent of the encounters with nuclei, the latter suffered disintegration.

International Conference on Radio Communication

RADIO engineers are looking forward anxiously to the international conference in Madrid on radio communication, which begins in September. In the *Wireless World* for Aug. 19 and 26, Noel Ashbridge, chief engineer to the British Broadcasting Company, states some of the problems of which a solution will have to be found. He confines himself to the broadcasting problem, and discusses first the problem of separating the frequencies and consequently the wave-lengths of the stations in Europe.

The existing agreement, known as the Prague plan, was put into operation by a large majority of the signatories in June 1929. It was decided that, so far as wave-lengths between 200 metres and 545 metres are concerned, the minimum separation between stations should be 9 kilocycles. This number was not selected on technical grounds but because it was the only hope of getting a general agreement. For the first year after the agreement the arrangement worked very well, only a few people who had signed the agreement failing to observe it in practice. During this year there were only a few stations which worked with a higher power than 15 kw.

Serious trouble started in November 1930, when Mühlacker, a high-power station, operated with a frequency adjoining that of London Regional. The result was immediate and severe jamming after dark on the London programme. The condition of affairs was very bad, because two years ago ordinary receivers were not nearly so selective as they are now.

The German engineers showed how the interference in the receiver could be cut out altogether, but the quality of the speech delivered was seriously affected. The solution adopted was to increase the separation between Mühlacker and London to 11 kilocycles. It is proved that if there is to be freedom from interference at the limit of the service area, the reproduction of frequencies of more than about 4000 cycles cannot be obtained and so the reproduction is not good.

It has been said that the response of a loud-speaker up to about 4000 cycles per second is sufficient for most practical purposes, and that, therefore, the interference problem does not now exist. Mr. Ashbridge states that, for really good quality reception, frequencies up to 7000 should be reproduced. A gramophone record reproduces something appreciable up to and a little beyond 5000 cycles, and yet the lack of the upper frequencies is quite noticeable to the critical ear. In future, this will doubtless be much improved. It would be a pity if broadcasting were permanently made inferior to the gramophone. Theoretically, the separation of broadcasting stations should be governed by the band of audio frequencies which it is necessary to cover in order to give full effect to the programmes.

If it is agreed to keep the 9 kilocycle separation, then those living in areas of high field-strength will get good quality service, whilst the others must have the higher frequencies cut off. If it were agreed to have a wider separation, then it would be necessary to reduce the number of stations in Europe as a whole. No one has ever pressed for a larger separation than 11 kilocycles, and experiments show that the range of reproduction can by this means be increased fifty per cent. The question of the limitation of the power of the various stations is a very difficult one. If they are too weak, we have 'fading'; if too strong, we cannot get the higher frequencies. It is difficult to say which is the more objectionable.

Calendar of Geographical Exploration

Sept. 7, 1298.—Marco Polo

According to Ramusio, Marco Polo was taken prisoner by the Genoese in a battle off Curzola in Dalmatia. Whether this was the exact date or not, it is at any rate certain that in 1298 Marco Polo was imprisoned in Genoa and that he there dictated his narrative to his fellow-prisoner, Rustician of Pisa. Marco Polo came of a family of Venetian traders; his father and uncle had visited the court of the Grand Khan, near Peking, on a journey which began in 1255. After their return, they again set out, taking Marco with them, in 1271. They travelled from Acre through Armenia, passed through Bagdad and Basra to Ormuz, turned inland and crossed Persia to Balkh. Thence they travelled across the Pamirs to Kashgar, went through Yarkand and Khotan to the south of Lob Nor, crossed the difficult Ordos desert and reached Peking. They remained in China for seventeen years, and returned by the sea route, a voyage which no European had ever before made from a Chinese port. Of all medieval travellers, Marco Polo is justly the most famous. To the unique opportunities given him by his long journeys and his prolonged stay in China he brought a vivid personality, keen and alert to notice everything of interest in his surroundings. In his narrative he shows a discriminating selection of the crucial facts of the geography and social and economic life of each of the many regions through which he passed. Thus, though six hundred years and more have passed since his book was written, it still holds readers by its charm and insight.

Sept. 7, 1787.—La Pérouse Strait

La Pérouse put in at Petropavlovsk in Kamchatka and thence sent Lesseps overland with the journals, notes, plans, and maps recording the work of his expedition. This foresight saved these most important observations from destruction, for after a letter of Feb. 7, 1788, from Australia, nothing more was heard of him until 1826, when Capt. Dillon found the wreckage of his ships on Vanikoro, an island to the north of the New Hebrides. La Pérouse sailed on Aug. 1, 1785, from Brest, to try to discover the north-west passage from the Pacific side. He reached Mount St. Elias, Alaska, on June 23, 1786, visited the Hawaii group, and discovered Necker Island. Thence he passed to the coasts of Japan, Korea, and 'Chinese Tartary', and discovered the strait between Sakhalin and the northern island of Japan which bears his name.

Sept. 7, 1837.—Adélie Land

The great French explorer, Dumont d'Urville, sailed from Toulon with two vessels, the *Astrolabe* and the *Zelée*, to search for land in the south polar regions. He attempted to follow Weddell's track, but was held up by pack ice and returned to make investigations in the Pacific. On Jan. 1, 1840, the vessels left Hobart, and discovered Adélie Land later in the month. D'Urville's work, both on this voyage and on a former one in 1826–29, added much to our knowledge of the geography of the Pacific, especially of the Fiji Islands, the Carolines, and the Moluccas. He also helped to chart more accurately the coasts of New Guinea and New Zealand. During his 1826–29 voyage he found evidence of the wreck of La Pérouse's vessel, which had disappeared in 1788, on the island of Vanikoro, one of the Santa Cruz group. On a voyage in the eastern Mediterranean he visited the island of Melos, and saw an old Greek statue which had just been unearthed. His keen appreciation of its beauty resulted in the acquisition by the Louvre of the famous Venus de Milo. This artistic sense led him to take the French artist Goupil with him to the antarctic; the resulting illustrations of his journal added much to its descriptive value, as well as to its beauty.

Societies and Academies

PARIS

Academy of Sciences, July 18 (vol. 195, pp. 193-292).—**L. Blaringhem**: Reappearance of fertility in a new variety of wild foxglove (*Digitalis purpurea*).—**Charles Achard, Augustin Boutaric, and Maurice Doladilhe**: The dilution of horse serum in electrolytic solutions. In an earlier paper it has been shown that by diluting 1 c.c. of serum to a volume l and measuring the optical density of the solution (h), then lh increases at first, passes through a maximum, and decreases to a limiting value. This work has now been extended to solutions containing salts.—**Emile Guyénot, W. Bartschi, and Mlle. K. Ponse**: The production of the yellow bodies studied by the method of transplantation of the ovary on to male guinea-pigs.—**J. Schauder**: The problem of Dirichlet generalised for non-linear equations of the elliptic type.—**J. Ottenheimer**: The displacement of water and the nature of the waves recorded in submarine explosions.—**D. Riabouchinsky**: Experimental researches on the formation of cavitations.—**Henri Mineur, Mlles. Renée Canavaggia and Marie-Louise Fribourg**: The correlation between the velocity of the star mass and their distance in the galactic plane.—**René Audubert**: The Debye-Hückel theory and electrophoresis.—**M. Pauthenier, Mme. M. Moreau-Hanot, and R. Guillien**: The charge of small

dielectric spheres in an ionised electric field.—**J.-J. Trillat** and **Th. v. Hirsch**: The diffraction of electrons by single crystals. The case of paraffin and the saturated fatty acids.—**Pierre Girard** and **P. Abadie**: The comparison of experiment and theory of dispersion in the Hertzian domain. The theory of Debye requires modification by the introduction of a factor representing the molecular constitution.—**Ch. Haenny**: The magnetic double refraction of salts of the rare earths in aqueous solution. Magnetic constants are given for twelve rare earths.—**Pierre Tarbès**: Method for the study of joining and expansion of glasses. Compensator for double refraction. If two glasses, possessing different coefficients of expansion are joined, the join may part at once, or possibly after several months. The method proposed measures the strains in the join by double refraction, using a special compensator.—**Léonard Sosnovski**: The polarisation of the fluorescence bands of cadmium vapour.—**Q. Majorana**: A new photoelectric phenomenon. Thin films of various metals deposited on glass (gold, silver, platinum, tin) show a variation in electrical conductivity on exposure to light. The effect was not observed with thin films of aluminium or zinc (see also NATURE, **130**, 241, Aug. 13, 1932).—**Mlle. Y. Cauchois**: A new method of X-ray analysis of crystalline powders utilising a monochromator with a curved crystal.—**Horia Hulubei**: The experimental study of the partial absorption of the X-rays. The author has attempted to repeat the experiments of B. B. Ray, but with negative results.—**Pierre Auger**: The emission of slow neutrons in the stimulated radioactivity of beryllium.—**Francis Perrin**: The constitution of the atomic nuclei and their spin.—**Mlle. M. Pernot**: The system mercuric bromide, potassium bromide, and water.—**Henri Muller**: The lowering of the eutectic point of ice–potassium nitrate, by acids, bases, and acid salts.—**Desmaroux** and **Mathieu**: Remarks on the structure of films of nitrocellulose with high nitrogen content.—**Charles Lapp**: The rotatory power of quinine in alcoholic solution. The specific rotatory power of quinine in alcoholic solution varies with the concentration. The facts are consistent with the hypothesis that the molecules of dissolved quinine form two groups, one in which each quinine molecule is associated with 40 alcohol molecules, the other group containing free quinine molecules.—**Lespieau** and **Guillemonat**: A new isomer of benzene, $CH_2 : CH . C : C . CH : CH_2$.—**Jacques Sordes**: The absorption in the ultra-violet of the hydrocarbons $(CH_3)_3C_6H_2(CH_2)_n . C_6H_2(CH_3)_3$.—**G. Hugel** and **M. Lerer**: The synthesis of alkyl aromatic hydrocarbons. The synthesis is based on the interaction of the hydrocarbon (napthalene, anthracene) with alkyl halide in liquid ammonia in the presence of sodium.—**R. Cornubert** and **G. Sarkis**: Contribution to the study of the extinction of the ketone function and the theories put forward to explain this phenomenon.—**Lucien Semichon** and **Michel Flanzy**: The application of chromic oxidation to some alcohols.—**Jacques de Lapparent**: The classification of the sedimentary clays.—**Henri Vincienne**: The flaky structure of the Ambérieu region (western edge of the southern Jura) and the age of the last Jurassic movements.—**Fernand Daguin**: A Cretaceous flora in the neighbourhood of Tissa (western Morocco).—**Maurice Hocquette** and **Mlle. Raymonde Villard**: The action of saturated ether vapour on the quiescent and dividing nuclei of the seedlings of *Raphanus sativus*.—**L. Plantefol**: The power of concentration of the cytoplasm. The formation of crystals by pollen grains, starting with neutral red.—**E. Miège**: The influence of various factors on the development of the inflorescence of cereals.—**B. Demetrović**: The effect of Mach's law. A discussion on the possibility of this effect being partly physiological and partly physical (diffraction).—**G. Tanret**: The hyperglycemic action of hordenine sulphate. Hordenine, in sufficient doses, possesses the hyperglycemic action of the true sympathomimetic substances (adrenaline, ephedrin).—**Marcel Avel**: The experimental analysis of the disappearance of the power of regenerating a head in the middle region of the body in *Lumbricus*.—**A. Macheboeuf**, **G. Sandor**, and **C. Nini**: Physico-chemical studies on the filtrates of acid-resisting bacilli of tuberculosis and of fleole.—**Mme. L. Gruzewska**: The α-lipase and amylase in the blood of some Crustacea.—**G. Champetier**: The fixing of water by cellulose. By a physico-chemical method, it is shown that cellulose fixes half a molecule of water per hexose group ($C_6H_{10}O_5$), whilst mercerised coaltar fixes double this amount.—**Maurice Piettre** and **André Guilbert**: The influence of electrolytes, especially sodium chloride, on the proteins of serum. The dispersion of myxo-protein in solutions of common salt cannot be explained by an adsorption of salt by the protein.—**Jacques Parrod**: The oxidation products of levulose in ammoniacal solution by methylene blue and atmospheric oxygen, at laboratory temperature. The products of this oxidation were 4-methoxy imidoazol, *d*-4-arabinotetroxybutylimidoazol, and a new substance imidoazol-4-formamide.—**Jean Cheymol** and **Alfred Quinquaud**: The exchanges of normal calcium in dogs deprived of their genital glands. Subsequent ablation of the parathyroids in the female dog results in the usual reduction of calcium in the serum.—**Joseph Lignières**: A new method of immunisation against diseases with filtrable viruses; its application to antiaphthous vaccination.

Cracow

Polish Academy of Science and Letters, May 2.—**K. Dziewoński** and **M. Brand**: The synthesis of ketones, acetyl derivatives of β-methylnaphthalene. By the interaction of acetyl chloride and β-methylnaphthalene in the presence of aluminium chloride, two isomeric ketones were obtained, which were identified. A diketone was also obtained.—**W. Friedberg**: The Miocene Pectinideæ of Poland and their stratigraphic value.—**Mme. N. Natanson-Grodzińska**: The plasticity of the instincts in the aquatic larvæ of Cataclysta.—**M. Konapacki** and **K. Ereciński**: The rôle of the vitelline sac in the metabolism of the embryos of *Syngnatus acus*.

Leningrad

Academy of Sciences (*C.R.*, No. 12, 1931).—**P. Schmidt**: A collection of flat-fishes from Fusan (Korea). The collection proved to contain twenty-four species, including one new to science, *Arnoglossus wakiayi*, sp. n. Fifteen of the species recorded belong to the Japanese fauna, six are more northern in their distribution, and only two can be considered tropical.—**G. Adlerberg**: The antelopes of northern Tibet and of neighbouring territories. A key is given to the Tibetan species of the genera *Pantholops*, *Gazella*, and *Procapra*, and notes on each species, with the discussion of geographical variation. *Gazella subgutturosa reginæ* subsp. n. is described from north-west Tsaidam.—**I. Starik** and **A. Gurevitch**: The adsorption of radium by glass. Description of experiments demonstrating that radium is adsorbed by glass in a neutral medium, while in an acid medium the adsorption is exceedingly small.

(*C.R.*, No. 13, 1931.)—**N. Filipjev**: Lepidopterological notes (11). Some forest pests from the Caucasian littoral of the Black Sea. Three species new to the Caucasian fauna are recorded, and one species new to science, *Platyptilia diversicilia*, is described.—**V. I. Gusev**: Bionomics of two species

of Microlepidoptera new to the U.S.S.R., *Evetria fessulatana* Stgr. and *Laspeyresia mariana* Zerny. The first of the two species develops in cones of *Cupressus*, the second in berries of *Juniperus*.—**B. Stegmann**: Origin of the bird fauna of the taiga. Pre-glacial fauna of the southern Siberian taiga was composed mainly of Sino-Himalayan elements, while that of the eastern Siberian taiga showed a very close relation with the fauna of North America.—**A. P. Semenov-Tjan-Shanskii** and **St. Breuning**: Three new species of the genus *Carabus* from Central Asia. Descriptions of *C. shokalskii* sp. n. and *C. znojkoi* sp. n. from Tjan-Shan, and of *C. redikortzevi* sp. n. from the Alexander range in Turkestan.—**V. V. Barovskii**: Notes on two species of beetles new to the fauna of the U.S.S.R., and description of a little-known species of the genus *Xylobanus* Ch. Waterh.—**S. Bernstein**: An example of a continuous function for which the Lagrange formula of trigonometric interpolation diverges.

(*C.R.*, No. 14, 1931.)—**A. Fersman**: The geochemical arcs of the Chibin Mountains.—**N. Filipjev**: Lepidopterological notes (12). A new *Hypochalcia* from the Ukraine. A description and figures of *Hypochalcia ukrainæ* sp. n.—**A. M. Popov**: *Anarrhichas orientalis* Pall., its systematic position and distribution, with notes on the species of *Anarrhichas* in the U.S.S.R.

SYDNEY

Royal Society of New South Wales, May 4.—**Edwin Cheel**: A review of systematology in botany (Presidential Address). In modern genetical literature, species and their subordinate units are regarded as populations. The units are not easy to define, and, because of this, certain biologists are of the opinion that the main criterion of an individual should be its physiological anatomy. Contrasts were given between the Jordanian methods of splitting the Linnean species into numerous elementary species or micro-species which appeared to be the same as what Lotsy termed 'group hybrids'. It has been found by extensive cultures that certain so-called 'pure lines' give a much higher percentage of mutation than others. From this result Nilsson draws the conclusion that the original 'pure line' did not contain only homozygotes, but also some sort of 'segregants' caused by the heterozygosity, thus upsetting the current theory of the production of pure, namely, homozygotic, lines by autogamous reproduction.

VIENNA

Academy of Sciences, April 28.—**Fritz Rieder** and **Elisabeth Rona**: Investigations on the ranges of the α-rays of actinium products. With RdAc the two prominent groups of lines with ranges of 4·7 and 4·35 cm., already seen by other workers, are observed. In addition, three other groups with lower intensities and with the ranges 4·6, 4·3, and 4·2 are found. These groups correspond with those recently detected by Curie and Rosenblum in the magnetic spectrum, but the α_1, α_2, and α_3 groups of these authors are not revealed by the author's procedure. The groups with ranges 4·3 and 4·2 were attributed by Curie and Rosenblum to AcX, but the results now obtained indicate with certainty that they belong to RdAc. Experiments with AcX preparations free from RdAc give the known group of range 4·3 cm., and also a second of range 4·1 cm. For AcC the groups with ranges 5·0 and 5·4 cm., observed by Rutherford, Wynn-Williams, and Lewis, are confirmed. With AcA, indications of a fine structure are obtained, since, in addition to the group of 6·47 cm. range, two weak groups with ranges of 6·35 and 6·60 cm. appear to be present. Moreover, with An a group with the range 5·6 cm. occurs, besides that with range 5·70 cm.

Forthcoming Events

Congress

AUG. 31–SEPT. 7

BRITISH ASSOCIATION FOR THE ADVANCEMENT OF SCIENCE (YORK MEETING)—continued.

Monday, Sept. 5.

At 10 A.M.—Prof. P. G. H. Boswell: "The Contacts of Geology: the Ice Age and Early Man in Britain" (Presidential Address to Section C).

Prof. Beatrice Edgell: "Current Constructive Theories in Psychology" (Presidential Address to Section J).

Prof. J. H. Priestley: "The Growing Tree" (Presidential Address to Section K).

At 5.30 P.M.—Mr. H. E. Wimperis: "Speed in Flight" (Public Lecture in the Co-operative Hall).

At 8 P.M.—Sir Richard Gregory, Sir Harold B. Hartley, Mr. Donald Gray, Dr. W. W. Vaughan, Prof. W. W. Watts, Mr. W. M. Heller: Discussion on "The Place of Science in the Education of Boys and Girls up to Sixteen Years of Age".

Tuesday, Sept. 6.

At 8 P.M.—Mr. C. C. Paterson: "Uses of the Photo-electric Cell" (Evening Discourse in the Co-operative Hall).

Problems in the Advancement of Archæology

IT is some time since anyone so closely identified with field archæology as Dr. Randall-MacIver has presided over 'Anthropology' at an annual meeting of the British Association for the Advancement of Science. It was, therefore, not without wisdom that Dr. Randall-MacIver elected to make in his presidential address a comprehensive survey of the practical problems and relations of archæological science as it stands to-day, rather than to deal with the results of recent research or of some specific investigation. Yet more than the mere passing of time called for some pronouncement on general principles in matters which have seemed to him to require comment. In the last decade archæological method and technique have developed rapidly; while the range of archæological activity has been extended enormously in many directions both in time and space. Areas which were once regarded as widely separated and studied in isolation, are now often viewed as links in a single chain. No longer can the methods and aims of archæological investigation in any country be regarded as of little concern to those who stand outside the national boundary. The field of archæological studies, in fact, has undergone, and is still undergoing, a process of unification which gives a peculiar significance to any pronouncement on the organisation and administration of research which is put forward with the authority of a presidential chair of a section of the British Association.

Dr. Randall-MacIver admitted that to some extent he had been influenced in his choice of subject by the example of his predecessor in the chair. Prof. Radcliffe-Brown last year, it will be remembered, reviewed the methods of field work in ethnography and its relation to the problems in synthesis of the comparative worker. The two branches of investigation in the field have this in common, that they now make heavier demands than ever before on the technical equipment of the investigator. The development of both ethnography and archæology owe much to the amateur; but in neither does investigation stand any longer at the stage at which the field notes or the rough spadework of the passing traveller are likely to make any contribution of lasting value to the respective branch of science in which he is interested. At best they may point the way to the skilled and trained investigator. This is not a question of amateur *versus* professional—it is to be hoped that research in Great Britain, which owes so much to

the amateur, will never be debarred to him—but of the trained man, amateur or professional, against the untrained.

In laying it down as a principle which should be universally recognised, that none but a properly accredited and trained archæologist, approved and supported by a group or committee of experts, should be permitted to excavate any site whatsoever, Dr. Randall-MacIver opens up a whole nexus of problems that confront modern archæology and its future development.

The more recent legislation for the protection of ancient monuments in Great Britain admittedly represents a great advance, and has gone some way towards ensuring the skilled excavation of valuable sites. On the other hand, the British Parliament is still sufficiently individualistic in its way of thinking to admit private rights of ownership which are not always in the best interests of the community in the long run, especially when they endanger evidence which might be invaluable to the future archæologist and historian.

Dr. Randall-MacIver's suggestion that part of a site upon which excavations are being made, or are in contemplation, should be set aside for future investigation, after some more or less lengthy period has elapsed, in the light of more fully developed knowledge—a suggestion, by the way, which was made by Sir Flinders Petrie some years ago—is a counsel of perfection which perhaps few investigators would have the strength of mind to follow without the restraint of superior authority behind them. That all, however, are not without some measure of self-denial in the face of posterity is indicated by the recent example of Mr. Alexander Keiller, at Windmill Hill, who, as recently announced, has reserved part of his valuable Early Bronze Age site for a future generation.

The practice of different countries in relation to their ancient monuments is far from uniform. Nor can it be said that vigilance is exercised everywhere in an equal degree in securing the observance of regulations. In some cases legislation, excellent in intention, fails in its object through laxity in translating its provisions into action. France, for example, would appear a case in point, at least until recently, according to the statement of French archæologists themselves. In this connexion, and in addressing a warning of the dangers ahead to those countries in which archæological investigation has scarcely attained the stage even of infancy, Dr. Randall-MacIver has two interesting suggestions to offer. One, an international question, is the formation of something in the nature of an archæological Court of Appeal—a scientific League of Nations; and the other, a concern of each country individually, but of enormous moment to archæological science at large, deals with control of the sale of antiquities—one of the strongest incentives to the private owner's destructive activities. Both classes of problem are difficult enough, though on paper it is perhaps the lesser which presents the greater difficulty in the tangle of conflicting interests impeding any straightforward solution.

It is not to the purpose here to enumerate or discuss the many problems of State regulation of archæological investigation on a nationalist basis. They are many and varied. That, in the interests of the advancement of archæological science, uniformity in dealing with them, according to the most advanced knowledge of the day, is urgently demanded, is a matter of common opinion in archæological circles. The suggestion of an archæological League of Nations, perhaps, may have reminded some of Dr. Randall-MacIver's audience of the relation of the League of Nations to matters other than political, and of the existence of a Committee for Intellectual Co-operation. On the other hand, a body less cumbrous to move and in closer touch with the actual situation in many, if not all, of its aspects, is the recently inaugurated International Congress of Prehistoric Sciences, which, although it will come into existence at intervals only, has provided, by the institution of research committees, a machinery for at least the initial stages of exploration of the problem.

The difficulty of dealing with the sale of 'curios' to the collector lies at the root of the greater number of the unauthorised or unskilful exploitations of the sites of antiquity. Were it possible to divert the stream of gold which pours into the pockets of the unscrupulous dealer, much of the destruction of valuable evidence which goes on, especially in the East, would cease automatically. On the other hand, the institution of official 'curio' shops for the sale of museum duplicates on the lines of that in Egypt, to which Dr. Randall-MacIver referred, to be effective would have to be a monopoly, and while it certainly would add materially to the revenue of the museums, which are never—at least, on the basis of their own calculations—liberally financed, would open the way to a number of abuses which it would be difficult to check. In Great Britain, the more liberal law of treasure trove, a genuine, if restricted, interest in the origin and history of finds among the artisan and agricultural classes, and the system of the loan of duplicates by the museums, meet the more serious

difficulties which Dr. Randall-MacIver has in mind. It must be admitted, however, that only rarely in Great Britain do we find antiquities of sufficient intrinsic value or of such obvious interest as to tempt the unscrupulous. But Great Britain's support, if only through the wide geographical distribution of her archæological interests, would be a potent factor in securing action on a common basis in those countries in which the question is one of more vital concern. May we add that the creation of a conscience in the collector offers a field for missionary effort to the ardent archæologist.

Dr. Randall-MacIver is no respecter of persons in his criticism, and he does not hesitate to chide the museums which press their excavators for impressive specimens to add to their collections, without thought of the value of the insignificant (in the museum display sense) for the purposes of science. In this matter we should perhaps recognise extenuating circumstances for those museums which must depend for their existence on the generosity of subscribers.

In connexion with museum excavations, reference was made to what, from the archæologist's point of view, is an evil almost equally grave—the delay in publication of results, a fault to which not archæological institutions alone are prone. It is impossible to say how far delay in making available material for comparative study may have hampered advance in archæological studies. The example of Sir Flinders Petrie, who for many years has made it an invariable rule to publish his results within the shortest time possible after his return to England in each year, shows that this is no impossible ideal, in so far as nothing more than a record of facts observed is required of the excavator in the first instance. A time limit for initial publication might well be a condition of any permit to excavate.

Dr. Randall-MacIver's presidential address raises so many points of broad general, as well as specialist, interest, that the commentary might well outrun the text in length, and yet not be exhaustive. Nothing, for example, has been said of his views on the relation of archæology as a science to other branches of the study of man. Yet to the archæologist of the future this offers both a guide and a warning. Unless the study, one of well-defined and rigid limitations in method, be followed in the spirit which Dr. Randall-MacIver advocates, a spirit of liberal co-operation with other disciplines, it risks a specialisation as arid and as sterile as the antiquarianism it has superseded. Of this, however, with our present school of workers in the field, there is little danger.

The Biology of Snakes and Amphibia

(1) *The Biology of the Amphibia.* By Dr. G. Kingsley Noble. (McGraw-Hill Publications in the Zoölogical Sciences.) Pp. xiii + 577. (London: McGraw-Hill Publishing Co., Ltd., 1931.) 30*s*. net.

(2) *Snakes of the World.* By Dr. Raymond L. Ditmars. Pp. xi + 207 + 85 plates. (New York: The Macmillan Company, 1931.) 30*s*. net.

(1) IN recent years marked changes have taken place in the outlook of biologists. Zoology must inevitably rest upon a foundation of morphology and classification; yet it is being increasingly realised that the study of animals demands for its development more fertile ground than is presented by the facts of anatomy and phylogeny. The living animal is a side of zoology which dominates to-day. Dr. Kingsley Noble strikes a distinctively modern note in the work under notice in directing attention to the physiological aspect of the subject, and he has been successful in covering the dry bones of anatomy with living flesh.

Part I. (458 pages) gives a well-balanced picture of the structure, physiology, and ecology of the various groups of Amphibia, which are considered in relation to one another and to their environment. The opening chapters deal with general problems—amphibian ancestry, the mechanics of development, evolution, and adaptation. The reader will early realise that within the limits of the class the wide variety of modifications in larval and adult forms is remarkable: members of various families have taken independently to the land for breeding purposes, and we find unrelated forms adapted respectively for crawling, swimming, leaping, burrowing, climbing, parachuting—examples of convergence which have in the past done much to confuse systematists in their attempt to arrive at a natural classification. Yet, as Dr. Noble shows in a survey of life histories (Chap. iii.), larval modifications and nursing habits frequently serve as an important guide to the affinities of species: thus the closely related *Phyllobates* and *Dendrobates* (formerly placed in separate families) are the only genera in which the males are known to carry the tadpoles on their backs.

A series of chapters on the structure and function of the vascular, digestive, nervous, and other systems considers each in some detail. Here there is a good section on the endocrine glands, embodying the result of much recent research on the important rôle played by hormones in the physiology of development, and it is interesting to note the

practical value to zoologists of the gonad-stimulating pituitary secretion, which "provides a ready means of obtaining embryological material at any time of the year". The four chapters on amphibian behaviour and ecology, written in an easy style, are informative and stimulating.

Part II. (85 pages) deals with the classification of Amphibia. Here there is a clear discussion of the mutual relationships of genera, free from an overwhelming mass of systematic detail; students who wish to pursue further this aspect of the subject are referred to the concluding bibliography of comprehensive taxonomic works. We have noticed a number of misprints, "blut", "tadpones" (p. 132), "inhabiti monguntain" (p. 167), "grog" (p. 407); and in the full index there is no reference to the treatment of neoteny on p. 294. Extensive bibliographies (of which there are some 58 pages) add much to the usefulness of the book, and the well-produced text-figures, many of them new, attain a high standard of excellence. Dr. Noble is to be congratulated upon the remarkable range of fact and theory which he has assembled in these pages, and the publishers upon a valuable addition to their "Publications in the Zoölogical Sciences".

(2) Snakes have claimed the attention of man from earliest times. Yet few groups of animals are so little understood by the layman, and few have been more indiscriminately persecuted. This book will help to clear away the prejudice and unreasoning hatred so generally directed against these reptiles, the majority of which are harmless to man, and many of which (by the destruction of rodents) are of economic value. Dr. Ditmars, who as curator of reptiles in the New York Zoological Park has had unique opportunities of studying the habits of serpents, combines the knowledge of a trained herpetologist with the experience of a field naturalist. He writes of snakes with authority, and the descriptions of his pets, both as captives and in Nature, are lively, informative, and intimate.

Dr. Ditmars assumes in his readers no previous acquaintance with the group. The book opens with several introductory chapters on distribution, habits, and classification. There is an interesting account of "The Giant Serpents". It is perhaps comforting to learn from an authoritative source that, in spite of the numerous reports of larger specimens, the record *proved* measurement of *Python reticulatus*—the world's longest snake—does not exceed 33 feet. Chapters vii. and viii. deal with the harmless species of the New and Old Worlds, followed by an abbreviated account of the Opisthoglyph (rear-fanged) snakes.

The remaining, and main, portion of the book is devoted to the appearance, habits, and distribution of poisonous species. These chapters contain some useful information on the treatment of snake-bite and on the physiological effect of specific poisons. The zoogeographical arrangement here will be especially appropriate in the hands of sportsmen, field naturalists, agriculturists, explorers, and others to whom a knowledge of these creatures is a matter of great practical value. It is perhaps unfortunate that the American species receive more than their share of attention; thus the Old World harmless snakes (Colubrinæ) are condensed into less than half the space devoted to those of the New World, and no mention is made of the commonest tropical and South African genera, such as *Boodon*, *Chlorophis*, and *Philothamnus*.

The book is well got up, and 160 splendid photographic reproductions, mostly from living specimens, are valuable as an aid to identification, and will repay careful study. They testify to the author's skilful technique as a photographer, and the portrait of a King Cobra (Plate 38) has high pictorial merits. HUGH B. COTT.

A Physiologist looks at Wild Animals

Emigration, Migration, and Nomadism. By the late Walter Heape. Edited with a Preface by Dr. F. H. A. Marshall. Pp. xii + 369. (Cambridge: W. Heffer and Sons, Ltd.; London: Simpkin Marshall, Ltd., 1931.) 12*s.* 6*d.* net.

DR. F. H. A. MARSHALL has edited and prefaced this posthumous work by the distinguished authority on the sexual cycle, Walter Heape. Few books cast a wider net for readers than this. The physiologist, the natural historian, the ecologist, the anthropologist, the psychologist, even the alienist, are concerned with the subjects treated. Yet how many of these, except the physiologist, will get past the first chapter? And how many physiologists will read the rest?

Many who would find the rest of the book of absorbing interest will be dismayed by this first chapter, for it includes many technical words which could have been avoided in a book of such wide appeal. Further, it is perhaps the most speculative part of the book, and was written before the author was acquainted with the work of Evans and others on vitamin E. The author foreshadowed the discovery of this vitamin. Recent research seems to show that he laid too great stress on nutrition as

a factor in the control of breeding seasons. It is true that certain of the higher animals do not breed in the absence of vitamin E, but evidence is not yet forthcoming that it is the absence of this factor in the non-breeding season which causes them not to reproduce.

There has been surprisingly little research on the actual cause of breeding seasons, presumably because the research must be physiological, and physiologists are mostly concerned with man and with animals which do not have breeding seasons in laboratories. Rowan and Bissonnette have, however, shown the importance of light as a controlling factor in the reproduction of birds, and other workers have obtained similar results with mammals. This recent research makes it probable that Heape has exaggerated the importance of the nutritional factor in the control of reproduction, despite the fact that in certain cases (as in sheep) food does play a part.

A wealth of natural history observations has been brought together in this book, bearing on the large-scale movements of animals. The author differentiates clearly between migration, which is a purposeful movement followed by a return, and emigration, which is the useless mass movement of the lemming and springbuck followed, not by return, but by death. The importance of territory in animal life is stressed. Eliot Howard's concept of the importance of territory in bird life is extended to almost the whole animal kingdom.

Heape saw clearly that if animals are machines, then they are vastly more complicated and unreliable and individual machines than most biologists are prepared to admit. The reader finds himself confronted with the problem of whether butterflies may be hysterical in certain circumstances, and animals are throughout regarded in a frankly anthropomorphic way. Heape does not hesitate to compare the movement of a pack of wolves with that of a nomadic tribe of men. Writing of birds, he says, ". . . it would seem to be clear that migration is not solely a matter of habit, or of instinct; reason may exert a part in it, and intelligence be accorded a more prominent place in the ordering of migratory movement than is generally acceded".

One cannot fail to be reminded of Elton's outlook, and to regret that Heape was not acquainted with his work. Especially is this so when the author is dealing with the periodicity of abundance in animals. Dr. Marshall has to some extent made good this defect, by giving brief accounts of Elton's work in footnotes. Heape thought that the regularly periodical emigrations of the lemming were due simply to overcrowding and scarcity of food. He overlooks the fact, pointed out by Elton, that animals may show the same periodicity on both sides of the Atlantic. Some unknown factor must evidently be at work. Otherwise, although widely separated animals might have a periodicity of approximately the same time-interval, they could not be expected to keep step in Canada and northern Europe.

The reader must be prepared for speculation if he is to enjoy the book. Even the most speculative will have qualms about a long description of the start of a butterfly emigration, which, as the author frankly admits, is only a phantasy. Many readers could advantageously skip large parts of the book, in which rather fragmentary information is given about a large number of species after a full and valuable discussion of a phenomenon of emigration, migration, or nomadism in the few forms on which much is known. The fragmentary parts might have been printed in small type, or placed in appendices, where they would no doubt have been valuable to a few, without taxing too heavily the skipping capacity of the majority.

The author's object in writing the book was to stimulate wider research on the comparative physiology of the reproductive system. If zoologists can be made to take an interest in function, or physiologists in wild animals, then his object will be achieved. JOHN R. BAKER.

Artificial Resins

Artificial Resins. By Prof. Johannes Scheiber and Dr. Kurt Sändig. Translated from the German by Dr. Ernest Fyleman. (The Specialists' Series.) Pp. vii + 447. (London: Sir Isaac Pitman and Sons, Ltd., 1931.) 30*s.* net.

AMBER for decorative purposes, shellac in the electrical industry and for gramophone records, copals for varnishes, rosins in soaps: all are natural resins. The importance of the part they play in the daily economy of the world is obvious; indeed, at least half a million tons of them are used annually. Latterly, they have been supplemented and even substituted at a rapidly increasing rate by substances made artificially by the systematic exploitation of numerous organic chemical reactions. Such products have many new economic potentialities, particularly since, with increasing experience, the control of the reactions which produce them becomes more accurate, so that the possibility is offered of varying their properties

widely and of increasing desirable qualities to a degree impossible with natural products. Already some forty thousand tons of synthetic resins are produced annually.

The book before us is a careful translation from the German, in which the authors' meanings have been reproduced as accurately as possible. Perhaps in consequence we find it somewhat involved in style and far from easy reading, even when allowance is made for the difficulties of the subject.

The first half is devoted to a general theoretical discussion of the various known forms of chemical polymerisation and condensation. The treatment will be found to be complete and of value to the now numerous workers in this field. The latter portion deals with the practical aspects of resin manufacture, discussing in turn the coumarone and aldehyde resins, the phenol-aldehyde resins, and the urea-formaldehyde condensation products. This section contains full references to the literature. Experts will find blemishes here and there, but they will readily pardon these in view of what is, after all, the main value of the book—its wealth of suggestive ideas.

The power of many organic substances, and of aldehydes in particular, to take part in chemical condensations has long been used in effecting chemical syntheses in the laboratory, where the aim has usually been to restrict the reaction to the formation of simple compounds and to avoid the production of resins. In the new industry, however, the formation of such resins is encouraged by working under conditions suitable to give products of complex and largely unknown constitution, but which under proper control are uniform from batch to batch. At first the practical operations were largely based on guesswork and experiment, but now the behaviour of the various types of unsaturated groupings is becoming understood, as is also the mutual influence of various radicals on them.

Looking ahead, there appears to be no boundary to what the synthetic resin industry may in time accomplish. Some enthusiasts even predict that our future furniture will be constructed from resins obtained by condensing formaldehyde, made from coke, with the phenolic constituents of low temperature tars, and that such material may largely replace wood in internal work. The wireless and gramophone industries are being largely built up on these resins. It is to be hoped, therefore, that the manufacture of all types of them will not be neglected in Great Britain. E. F. A.

The Enjoyment of Nature

The Open Air Year: an Anthology of the Seasons selected from The Times. Pp. xii + 242 + 20 plates. (London: *The Times* Publishing Co., Ltd., 1932.) 7*s*. 6*d*.

TO this volume of papers reprinted from the *Times*, Viscount Grey of Fallodon contributes a singularly happy introductory essay which in itself supplies unity or harmony to the book. There is probably little or nothing in the papers which is not already well known to specialists in the various subjects. There are, however, many things in this book about common country objects which, as Viscount Grey points out, are not common knowledge even to dwellers in the country, and perhaps still less to that increasing body of the public which is interested in outdoor Nature. In an attractive style and with a literary charm that is in no way inferior to that of such writers and observers as Richard Jefferies or W. H. Hudson, they convey a good deal of accurate scientific knowledge which should enable the visitor to any of the places or scenes described to discover and enjoy aspects of which he was previously unaware. The book is a worthy companion to Cornish's "Wild England of To-day" or Edmund Blunden's more recent sketches, "The Face of England".

In the true sense of the word, we have in this book popular science of a high order, and the reflection occurs in passing that the popular knowledge of physical as well as of outdoor Nature or natural science might well be encouraged by its exposition on similar lines. The writings of T. H. Huxley alone afford sufficient evidence that the accurate but lucid exposition of the more scientific aspects of biology is not too herculean a task for human powers. There are few more urgent needs at the present time than for first-class expositors in every branch of science who can link together as felicitously as in this book the accurate description or analysis of scientific observations or facts with a literary skill which has an intrinsic popular appeal.

In the introduction to which we have already referred, Viscount Grey, commenting on an observation in the essay "The Flame of Autumn", that the colours of autumn leaves cannot be robbed of romance by being harnessed to some utilitarian purpose, is moved to the reflection that the utilitarian purpose is secondary in the design of Nature, and to emphasise both the infinite beauty of the world and, separate from but inseparably connected with this, the power of man to perceive this beauty and to be moved by it. It is at least possible that our

present lack of the needed expositors in many branches of science is due to loss of this vision of beauty through the concentration on analytical or synthetic methods. It is only when we are able to perceive and respond to the beauty of our subject and to see it in some true perspective that we can expect to receive the power to expound to others, in language understood by all, the vision vouchsafed us, or the results obtained and the methods by which they were obtained. So far as outdoor Nature is concerned, volumes such as that under review, in kindling this vision and love of beauty, may also assist in the formation of a public opinion intelligent and strong enough to secure the action which in so many quarters is sadly needed, if serious depletion of the flora and fauna of our countryside is to be prevented and its beauty spots secured from irreparable damage in the local interests of some supposed utilitarian or business scheme.

Short Reviews

Biologie des Radiums und der radioaktiven Elemente. Von Prof. Dr. Julius Stoklasa. Unter Mitwirkung von Dr. Josef Pěnkava. Band 1: *Biologie des Radiums und Uraniums.* Pp. xiv + 958. (Berlin: Paul Parey, 1932.) 74 gold marks.

Several books have been written on the biological effects produced by the radiations from radioactive bodies, and they have presented the chief characteristic changes in living things in the relationship of such changes to the main issues of radiological treatment. It is fairly generally admitted now that although the main effect of the radiations is a direct one upon the tissues immediately irradiated, other effects are produced in an indirect way which may be of great importance in the final result of any radiological exposure. The aim of the authors in this exhaustive work (another volume is foreshadowed) is to present these biological effects from an entirely different point of view, and about two-thirds of the present volume is devoted to the description of elaborate methods of estimating the effects of the rays on vegetable life. It is only when p. 640 is reached that the animal kingdom receives attention, and even in this section the authors give their fullest consideration to the types of biological change that are most conspicuous in plant life, namely, those which regulate respiratory exchange.

Many of the experimental methods described in the dominant section of the book have been devised by one of the authors, and they leave the reader with little doubt of the profound effect which can be produced by radioactivity on young plants and seeds. The literature of a few years ago on this subject revealed acute differences of opinion among experimenters as to whether the radiations could stimulate cell life, and the authors have done a great service in getting together a comprehensive series of tests which serve to show how many factors involved in the processes of normal growth have to be taken into consideration before the term stimulation can safely be applied to any particular phase of the growing organism.

The book is a most careful compilation and should prove to be of great use as a reference book on these particular biological effects, even though there is very little direct reference to their significance in modern radiotherapeutic methods.

Dynamics of Airplanes and Airplane Structures. By Prof. J. E. Younger and Prof. B. M. Woods. Pp. xiii + 263. (New York: John Wiley and Sons, Inc.; London: Chapman and Hall, Ltd., 1931.) 17*s.* 6*d.* net.

This is distinctly an American students' textbook that has no counterpart in Great Britain. It is obviously the work of skilled mathematicians, who have applied their knowledge to the investigation of some of the peculiar problems of the aeroplane. They have evidently treated their subject *multum in parvo*, and have rigidly resisted the temptation to stray from the application of mathematics to the problems before them, into the more philosophical outlook, which is so often the case with books of this description. The reader's taste will decide whether or not this is an advantage. This narrow outlook is not an ideal training for the student, but on the other hand it must be admitted that the authors do 'deliver the goods' and in a volume of reasonable size. Judged from the point of view of the English educational system, it is recommended for reading to a student who, having already studied the fundamentals of aeronautics, will benefit by approaching the subject from a somewhat different point of view, before taking up the deeper detailed investigations, as published in monographs such as the Aeronautical Research Committee Reports and Memoranda.

The text is divided into three parts. Part 1, "Simple Dynamics of Airplanes", deals with mathematical principles, and uses the aeroplane for the provision of illustrative examples. Part 2, "Advanced Dynamics of Airplanes", treats the various aspects of the machine in flight, including a useful study of stability. Part 3, "Special Problems", deals with special problems such as dynamic loading, periodic oscillations, vibration, flutter, etc., all of which are handled according to the most modern accepted theories.

The book has a useful decimal system of reference, both in paragraphing and numbering of formulæ, which makes cross-reference particularly easy. The index refers to page numbers.

Mendelism and Evolution. By E. B. Ford. Pp. xii + 116. (London: Methuen and Co., Ltd., 1931.) 3*s.* 6*d.* net.

This little book presents with great clearness and precision the actual position of modern genetics in its relation to the problem of evolution. It represents a review of the whole field of the subject and of the most important theories developed around it in recent years. Each aspect of the problem is considered with reference to a wealth of data, which should prove invaluable to students who have not

the time to collect for themselves the information rather widely scattered in the literature of the science, and necessary to obtain a grasp of the present state of the problem.

In a preliminary chapter the fundamental laws of the particulate theory of inheritance are crisply and clearly set forth, for which those who have not made a study of genetics will be grateful. The interaction of heredity and environment is then considered, with special emphasis on the internal environment provided by the gene complex. This is aptly followed by a review of the theory of the evolution of dominance and recessiveness. The question of the rôle of the cytoplasm in inheritance is well handled, and the adequacy of Mendelian inheritance to sustain the processes of evolution is demonstrated. The importance of geographic and also of genetic isolation with regard to the origin of species is well illustrated. Mr. Ford has, in fact, treated a very many-sided subject in a remarkably thorough and satisfying manner. A glossary which includes all technical words not explained in the work itself places this excellent book fully within the appreciation of the layman.

Chemistry in the Service of Man. By Prof. Alexander Findlay. Fourth edition. Pp. xviii + 355. (London, New York and Toronto: Longmans, Green and Co., Ltd., 1931.) 6*s*. net.

WRITERS have called this a chemical age: it is certainly a period of chemical evolution, and side by side with a rapid advance in the science of chemistry there is great progress in its application to material things. Every layman participates in the benefits, and it behoves most of us to have some understanding of the how and the why of them. The conversation books of a former generation taught us in an entertaining way of the fruits of the earth and even of chemistry: to-day they are replaced by such books as that of Prof. Findlay, now in its fourth edition. He has somehow achieved the task of compressing everything into a very small compass, and yet produces a book which is eminently readable by an average person who seeks to enlarge his curiosity after the works of Nature. It is a book which should be widely read: in a more enlightened age one would expect a long notice of it to be treated as a feature by the literary reviews--surely a knowledge of what things are is of more importance than the history of a particular period, or the life of an eminent statesman, soldier, or courtesan? E. F. A.

Handbuch der Pflanzenanatomie. Herausgegeben von Prof. K. Linsbauer. Lief. 27. Abt. 1, Teil 2: *Histologie.* Band 4: *Die Epidermis.* Von K. Linsbauer. Pp. viii + 284. (Berlin: Gebrüder Borntraeger, 1930.) 29·40 gold marks.

THE section of this handbook upon anatomy that deals with the epidermis has been written by the editor of the series and might serve as a very good example of such encyclopædic work at its best. The epidermis is considered from the point of view of the morphology and detailed structure of the individual cells, with special sections upon the thickening and pitting of the wall and of the wavy contours that characterise the anticlinal wall in many cases, etc.

The chemistry of these membranes—slime formation, lignification, the nature of the cuticle and of wax excretions—receives very adequate attention.

The protoplasm of the epidermal cells and the various inclusions that have been reported are fully dealt with. The development and regeneration of the epidermis are adequately treated, so far as is permitted by the lack of attention these problems have had up to the present. The function of the epidermis leads to a full treatment, as an absorbing system, of the root surface and of the root hairs, but such physiological subjects, as also theories of light perception by epidermal cells, are only considered so far as they have led to re-examination of structural features of epidermal tissues. The root hair receives much attention when considering the epidermis as an absorption system, but the epidermis as a protection against evaporation receives less attention, and the problem whether hairs on the shoot epidermis hinder or help evaporation is left alone. Stomatal apparatus is evidently excluded from the scope of the monograph.

Studies on the Genus Pythium. By Velma Dare Matthews. Pp. v + 136 + 29 plates. (Chapel Hill, N.C.: University of North Carolina Press; London: Oxford University Press, 1931.) 13*s*. 6*d*. net.

MISS V. D. MATTHEWS' book gives a very complete account of the genus *Pythium*. The author collects information of the methods and media for culture, discusses distribution and habit, the production of mycelium, sporangia, conidia, zoospores, and sexual organs, and considers taxonomic characters. The genus *Pythium* is taken as it was originally established by Pringsheim, though its vicissitudes since that time are also enumerated. A key to the species is given, and each one is described in detail, with such physiological characters as are known. The host-range is also enumerated, and the book includes twenty-six plates of line drawings and an extensive bibliography. The academic or economic mycologist will find the book a useful work of reference.

Agricultural Policy in South Africa. By Prof. H. D. Leppan. Pp. 101. (Johannesburg: The Central News Agency, Ltd., 1931.) 6*s*.

PERHAPS the chief interest of this book is the summary of the natural conditions in South Africa: the accounts of the soil, climate, water problems, and others. Few countries in the world are more interesting to students; within a comparatively short range one finds the moist temperate climate of the southern part of Cape Province, the semi-arid conditions of the Karroo, the desert of Griqualand, the open steppe-like country of the veldt, and the tropical luxuriance of northern Natal. Farther north comes the park-like country that stretches away to the equator and beyond. All these natural features react on the agriculture and bear on the agrarian policy best suited to the country. The author's discussion will be found of interest, even to those not particularly concerned with the agricultural industry.

Radio Observations during the Total Solar Eclipse of Aug. 31

THE radio observer of eclipse phenomena is subject to one important limitation which at once denies him the most spectacular successes and safeguards him from the most acute disappointments of the optical observer. He cannot make direct observations on the solar phenomena, but is restricted to a sort of indirect photometry of the ionosphere, a region already subject to such wide and ill-understood variations that no completely conclusive determinations are likely and no fully satisfactory control observations possible. At best, then, the agreement between the temporal sequence of radio phenomena and the sequence predicted from theories of the media will give strong support to one of the competing theories; at worst, a correlation of substantial magnitude will be submerged in random variations.

The eclipse of Aug. 31 was ill-situated, in place and time, for the mitigation of these difficulties. The line of optical totality did, indeed, fall happily for detailed observation, but totality was reached at a time of day when the diurnal curve of ionisation density in the ionosphere was already likely to be falling steeply, so that the temporary withdrawal of the ionising effect of ultra-violet light could only make the existing slope steeper, and the renewal of the effect could only be referred to a lower datum point. The centre line of the anticipated particle eclipse [1] was likely, on any probable assumptions of particle velocity, to lie mainly over the ocean, and the only observing stations near the centre line (computed from the most probable velocity) were the necessarily under-manned and under-equipped Polar Year stations on the eastern coast of Greenland. These stations were still more heavily handicapped than were the American stations by the steeply falling diurnal curve, while western European stations were near the very sunset limit of eclipse, and consequently observed in the unstable and variable conditions which have, from the earliest days of radiotelegraphic observation, been known to characterise the sunset period.

The crucial problem to be examined was, of course, the discrimination between ultra-violet light and corpuscles as ionising agents for the two main regions of the ionosphere. There was substantial agreement that the Appleton region, above 200 km., probably owed most of its ionisation to ultra-violet light, but while Chapman inclined to the view that the Kennelly-Heaviside region, at about 100 km. height, was ionised by neutral solar corpuscles, Appleton and Naismith "accept ultra-violet radiation as one of the causes, if not the chief cause, of the ordinary diurnal replenishment of the ionisation in Region E" (the Kennelly-Heaviside region), and "regard the solar stream of neutral particles as causing the extraordinary effects on abnormal days". It may be remarked that further theoretical development of this view would appear to be necessary to account for the remarkably limited single range of height within which these mixed agencies develop maximal ionisation density. Further work must also take account of the redistribution in the horizontal of that ionisation which results from the injection of ionising agents into regions outside the vertical column of ionosphere directly sampled by the modern technique of short-base echo sounding. The replenishment of ionisation in the Kennelly-Heaviside region after sunset, noticed by Appleton and Naismith [2] in England, by Schafer and Goodall [3] in the United States, and by Ranzi [4] in Italy, may possibly be referred to this horizontal redistribution.

The radio observations made in connexion with the total solar eclipse of Aug. 31 were of three kinds. The first and most directly interpretable class contained short-base echo experiments designed to give direct evidence of the state of ionisation vertically above the experimental stations. These stations were, in some cases, existing research establishments, but the Canadian authorities set up special stations at points vertically under the lines of optical totality for the two principal regions (these lines lying somewhat south-west from the line of totality at ground level), and Canadian and United States expeditions also proceeded to points as far eastward as were conveniently attainable on the American continent, in order to sample the particle eclipse. The second class of observation was made on long distance signals specially emitted for the purpose on frequencies and trajectories chosen to enhance the relative importance of one or other of the ionised regions in its normal and 'eclipsed' states. The collaborations amongst the American Telephone and Telegraph Company in the United States and the Post Office and Department of Scientific and Industrial Research in Great Britain, and between the British and Canadian Marconi Companies, belong to this category. The third class of observation dealt with the quality of reception of signals normally available, and included the considerable body of amateur collaboration in two continents, the results of which will doubtless become available at an early date.

It need scarcely be said that detailed observational results and considered conclusions are not yet available for discussion. But by the courtesy of the many authorities concerned the preliminary data, specially communicated for publication in NATURE, may be summarised here. The data will be taken in geographical order, from the eastern fringe of the particle eclipse to the western fringe of the optical eclipse.

Dr. Van der Pol, observing at Eindhoven, was so situated that the particle eclipse (here regarded as an eclipse of 1600 km./min. particles) was partial only, and was overtaken halfway through by the incidence of ground sunset. It was, then, not surprising that in such unfavourable geographical conditions no marked anomaly in Kennelly-Heaviside layer conditions was observed during the eclipse.

The two stations of the Department of Scientific and Industrial Research, namely, the Polar Year station established, in co-operation with the British

National Polar Year Committee and the Norwegian Committee for Cosmic Physics, at Tromsö, and the Radio Research Station, Slough, were, despite their geographical separation of 1330 miles, similarly situated in respect of the particle eclipse, which ended about the time of local sunset at both stations. Prof. Appleton's station at King's College, London, and Mr. J. A. Ratcliffe's station at the Cavendish Laboratory, Cambridge, both working, as always, in close co-operation with Radio Research Station, formed with Slough a group of stations thus unfavourably situated in south-east England, each of which undertook a distinct section of a single observational programme of short-base echo work. The Post Office stations at Dollis Hill, Baldock, and Cupar, and the Slough station, participated similarly in a single programme of organised observation on trans-Atlantic radio channels.

The Tromsö observations were complicated by the fact that the ionosphere was in the process of recovery from a severe magnetic disturbance. Had the station been farther from the sunset fringe, this magnetic disturbance might have been of importance in the study of the particle eclipse, but the general result of the superposed conditions was that, on a preliminary survey at least, the Tromsö record gives no suggestion of eclipse effects.

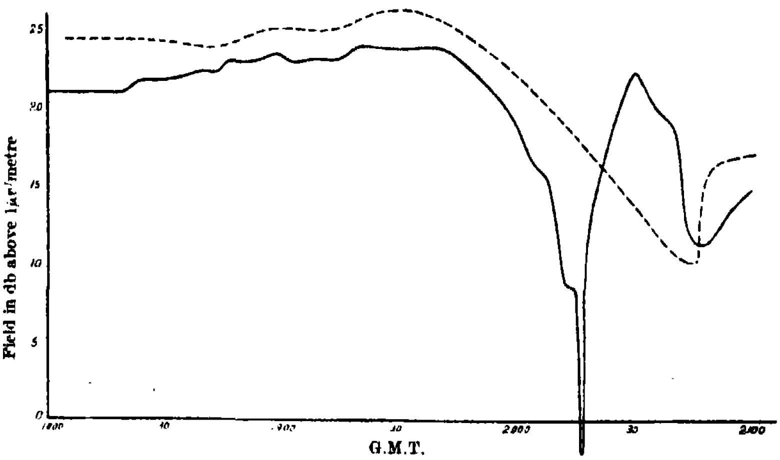

FIG. 1.—Field strength measurements taken at Cupar Radio Station on 60 kc./sec. of Rocky Point, U.S.A., transmissions. — — — — — Aug. 30; ———— Aug. 31.

The results from Cambridge, London, and Slough may conveniently be considered together. Cambridge and London, concentrating special attention on the Appleton layer, agreed in showing that the ionisation density in this layer increased between 1800 and 1900 G.M.T., suggesting that any effect of the particle eclipse on this layer was (1) over before 1815, (2) absent, or (3) overlaid by another cause of increased ionisation density. A notable decrease of ionisation observed by London about 1700–1720 might have supported (1), suggesting the eclipse of unexpectedly slow particles of low penetrating power, but the occurrence of a similar effect of less magnitude, on the succeeding control evening, was against this interpretation. On the other hand, Cambridge found that the electron density in this layer fell to a selected critical value, low enough to permit the escape of 70 metre waves, nearly an hour earlier on the eclipse date than on each of the adjacent control days. This time of critical value was confirmed by London. A slight rise in the effective height of the Appleton layer was observed at Cambridge at 1830 on Aug. 31. There are here two very slender suggestions that the cutting off of the corpuscular ionising agent permitted recombination to bring about an exceptionally early night condition, and increased the height to which it was necessary to proceed before finding a particular ionisation density.

Slough concentrated attention especially on the Kennelly-Heaviside region, about which Cambridge and London were able to supply confirming evidence. It is firmly established by the combined data that the ionisation density in this layer was notably lower in the late afternoon of Aug. 31 than on Aug. 30 or Sept. 1; the equivalent electron density being about 2×10^5 electrons per c.c. on both control days. At 1815 on Aug. 31 the value of $2{\cdot}5 \times 10^5$ was momentarily attained, but in general the value lay below $2{\cdot}0 \times 10^5$. At 1851 the density was below $0{\cdot}6 \times 10^5$, at 1905 this value was exceeded, and from 1940 to 2030 the average density was of the order of 1×10^5. There is, then, definite evidence of a relatively low ionisation density at the time of the particle eclipse, followed by a notable rise. This low density at 1830 has no counterpart on the control days, but the rise between that hour and 1900 is paralleled by the events of Aug. 30.

The British observations on trans-Atlantic signals were made on frequencies of 13,390 kc./sec. (wave-length 22·4 m.), 8665 kc./sec. (34·7 m.), and 60 kc./sec. (5000 m.) emitted from the stations of the American Telephone and Telegraph Co. at Laurenceville, of the General Electric Company at Schenectady, and of the American Telephone and Telegraph Co. at Rocky Point respectively. The 13,390 kc./sec. channel was watched at Baldock and Cupar, and the ray angles and state of polarisation were measured at Slough; the 8665 kc./sec. channel was watched at Slough; while the 60 kc./sec. channel was watched at Dollis Hill, Baldock, and Cupar.

It may be said at once that on the higher frequencies, no phenomena were observed which lay outside the normal range for the average afternoon; the impossibility of isolating any eclipse event on these channels is emphasised by a very great contrast in behaviour from one control day to another. A complete fade-out between 1951 and 2000 G.M.T. on Aug. 31 was observed on the 13,390 kc./sec. channel, but, as just indicated, no special significance can be attached to it.

The 60 kc./sec. channel, however, is subject to a

very much smaller range of normal variation, and the fact that this frequency range must involve the Kennelly-Heaviside region as an important element in propagation gave it an especially important place in the programme. Dollis Hill and Baldock did not observe any important anomalies on the eclipse date or on the control days. Cupar, on the other hand, experienced a complete fade-out between 2015 and 2018 G.M.T. on Aug. 31, followed by a recovery to a relatively high signal level at 2030. This sequence of phenomena was the only departure from a very close similarity between the variation curves for Aug. 30 and 31, as shown in Fig. 1. A complete fade-out of this type is such a rare event on the 60 kc./sec. channel that it is certainly significant, and the time of its occurrence, although somewhat surprisingly early, is so close to the time of minimum illumination of the lower ionosphere over the early part of the trajectory, that it may be concluded with some confidence that we have definite evidence of an ultra-violet eclipse effect on the Kennelly-Heaviside layer.

Details of the observations made by the Dutch and French Polar Year parties at Angmagssalik and Scoresby Sound respectively are, unfortunately, not yet available.

The Canadian joint observations are summarised in a special communication kindly cabled by Prof. A. S. Eve. The special expeditions sent to Vanleek Hill, Ontario, and to Kingston, Ontario, under the direction of Dr. J. T. Henderson and Dr. D. C. Rose respectively, report distinct losses in the ionisation of both the Kennelly-Heaviside and Appleton layers during the period of optical eclipse. The special expedition to Corner Brook, Newfoundland, also under the direction of Dr. Henderson, gives supporting evidence.

The observations at all three Canadian stations give no indication of any effect of corpuscular eclipse. The Nova Scotian expedition of the U.S. Bureau of Standards had not reported at the time of writing.

The Northern Electric Company found no intensity change in 500 metre signals between Ottawa and Montreal, while the Canadian Marconi Company found no definite changes which could be ascribed to the eclipse in 22·37 metre transmissions across the Atlantic.

Observations at the Bureau of Standards, Washington, revealed effects on both Kennelly-Heaviside and Appleton regions. The methods adopted enabled a measurement to be made of the critical frequency just capable of penetrating each region at vertical incidence. Penetration of the lower region would be indicated by a sharp change in the retardation time of the radio echo, from that corresponding to the lower region to the much higher value corresponding to the upper region. Penetration of the upper (and more highly ionised) region would be indicated by the absence of an echo on the relatively high frequency which had first penetrated the lower region without measurable reflection, but had still, below the critical value, been reflected from the Appleton region. The Bureau of Standards reports that the conclusions to be drawn from the observed effects on the Appleton layer are still under consideration. For the Kennelly-Heaviside layer, however, the critical frequency of penetration was lower by about 1000 kc./sec. at the end of optical eclipse than before and after eclipse. The minimum critical frequency was reached about five minutes after the maximum of partial optical eclipse at Washington. This decrease of critical frequency indicates that the partial ultra-violet eclipse at Washington, with a duration of about an hour and a half, was accompanied by a very slightly lagging reduction of something between 35 and 60 per cent in the density of ionisation in the Kennelly-Heaviside region.

The provisional conclusions to be drawn from this assembly of data may now be summarised.

Optical Eclipse.—The evidence from the U.S. Bureau of Standards, National Research Council of Canada, and British Post Office establishes beyond any doubt the importance of ultra-violet light as a principal ionising agent for the Kennelly-Heaviside layer.

The evidence from Canada establishes a similar ultra-violet effect for the Appleton region, and the Bureau of Standards data probably support this evidence.

The evidence from European short-base echo stations was not expected to bear on the optical eclipse, nor does it do so.

Particle Eclipse.—No evidence is yet available from the only stations even moderately favourably situated for observations on the effects of the particle eclipse.

The Canadian and United States stations, unfavourably situated in place (and the Dutch station, unfavourably situated in place and time), show no effects at all suggestive of particle eclipse.

The British stations, unfavourably situated in time, give very slight suggestions of effects from the eclipse of particles of velocity somewhat below the 1000 miles per minute assumed in the computations of track and time.

In the light of all available evidence, weighted according to situation, the significance of ultra-violet light as a principal ionising agent for the ionosphere as a whole is established; the possible significance of neutral corpuscles is not established, but is not wholly excluded; it remains to be tested under more favourable conditions and in the light of our rapidly growing knowledge of the climatology of the ionosphere.

This discussion opened with a summary of the defects, in time and place, of the 1932 eclipse from the point of view of ionospheric observation. It may appropriately close with an indication of the merits of a 1933 eclipse. Chapman has shown that the student of the ionosphere is less interested in the distinction between total and nearly total eclipse than is the astronomer. The annular eclipse of Aug. 21, 1933, is of sufficient magnitude in respect of ionisation effects, and it has the overwhelming advantage that maximum eclipse for light and for particles alike can be observed in inhabited land areas at times when the diurnal curve of ionisation

density in the ionosphere is rising comparatively slowly or is near a stationary point: that is, the optical eclipse might be observed in the morning, but well after sunrise, the particle eclipse near noon. The low latitude of the eclipse track suggests another considerable advantage, the eclipse phenomena unrolling at such a low speed that the cumulative effects on ionisation may well outweigh the 7 per cent defect in magnitude of the eclipse. It would appear most desirable that an adequate organisation should be worked out for observations on the optical eclipse near Delhi, with corresponding observations on the particle eclipse.

The Superintendent of the Radio Research Station, Slough, would be grateful for information as to the station of origin of pulse signals on a frequency of 3·56 mc./sec. (pulses at 50 per sec.) which were accidentally observed at Slough during the control experiments for the eclipse. The pulse signals ceased at 2020 G.M.T. on Sept. 1 and at 2100 on Sept. 2. The echo pattern, showing marked magneto-ionic splitting, was recorded simultaneously with that from local pulses; the comparison of distance and direction data might yield useful results.

Current Constructive Theories in Psychology *

By Prof. BEATRICE EDGELL

ON Aug. 29 there occurred the tercentenary of one who is often called 'the father of English psychology', John Locke, 1632–1704. His "Essay concerning Human Understanding" is primarily a theory of knowledge, not a system of psychology, but none the less there is much of psychological interest in the Essay, and it has had a profound influence on empirical psychology in the eighteenth and nineteenth centuries. We may regard it as a misfortune that what he described as a "historical plain method" should have been interpreted as a genetic study, and that his doctrine of simple and complex ideas should have been translated into a doctrine of psychological elements and compounds; but such has been the case. Historians trace a straight line of descent from the Essay of Locke to the "Analysis of the Phenomena of the Human Mind" by James Mill, and thus claim Locke as a founder of the Association school.

It may seem a far cry from 1632 to 1932, but I want to consider some of the differing constructive theories of learning and knowledge offered by the psychologists of to-day in the light of the unreconciled methods and principles which find expression in the Essay.

We find first and foremost in the Essay a confusion of logical and psychological analysis; secondly, we find a theory that attributes the union of discrete ideas to their accidental association in time, introduced as an afterthought to the theory that ideas are united by the perception of their connexion or repugnancy.

To begin with the confusion of logical with psychological analysis. As Prof. Gibson has pointed out in his book "Locke's Theory of Knowledge", at the time at which Locke was writing, the distinction between the elements of knowledge attainable by logical analysis and the simple beginnings of knowledge attainable by genetic study was a distinction which it was wellnigh impossible for a writer to draw. Growth and development were conceptions which had a very different colouring from what they have for us to-day. They were, moreover, conceptions which had no literal application to knowledge. Knowledge for Locke was a structure the validity of which could be tested by taking it to pieces. Just as a logical analysis of the ultimate items into which, say, a building could be resolved and an inquiry into the material out of which it arose might lead one to much the same catalogue of stones and beams, so a logical analysis of knowledge into its elements seemed to have the same issue as an inquiry into the beginnings of knowledge. That which is simple in its content is easily confused with that which is simple in its origin. It is this confusion which lays Book II. of Locke's Essay open to much misunderstanding. Having in Book I. denied that mind is possessed of ideas at birth, and having claimed that all knowledge is founded upon, and derived from, experience, Locke seems by his account of the 'simple ideas' of sensation and reflection and of the 'complex ideas' built upon them to be offering a psychological constructive theory of knowledge.

There is much of great psychological value in this second book: Locke's frequent appeal to concrete illustrations, his references to children and animals, the famous citation of Molineux's problem whether a man whose sight was only restored to him in adult life would be able to distinguish by sight between a sphere and a cube. The book also contains his striking chapter on retention, vivid through its analogies but of paramount importance for psychology by reason of the statement added in the second edition: "This laying up of our ideas in the repository of the memory signifies no more but this, that the mind has a power in many cases to revive perceptions which it has once had, with this additional perception annexed to them, that it has had them before, and in this sense it is that our ideas are said to be in our memories, when indeed they are actually nowhere; but only there is an ability in the mind when it will to revive them again, and as it were paint them anew on itself, though some with more, some with less difficulty; some more lively, and others more

* From the presidential address to Section J (Psychology) of the British Association, delivered at York on Sept. 5.

obscurely " (II. x. 2). Here there is a glimpse of a conception which might have done much to correct the atomism encouraged by the 'blank paper' and 'cabinet' metaphors in other passages. When mind is compared with an empty cabinet which is furnished by the simple ideas of sensation and reflection, simple ideas are being treated as the psychological origin of knowledge. When, on the other hand, Locke tells us that simple ideas are unanalysable, are not distinguishable into different ideas, and are those in which men agree when they clear away verbal misunderstanding, we have simple ideas as the materials of knowledge in the logical sense. If we look at the simple ideas listed together, we find the same confusion: the items 'colour', 'sound', 'pleasure', 'pain' might be interpreted as psychologically simple, but what of the items 'existence', 'unity', 'power', 'succession'?

In his account of complex ideas, Locke starts with what purports to be a psychological account of how they are formed—namely, the operations of compounding by putting together several simple ideas, and of abstracting by "separating them from all other ideas that accompany them in their real existence". These operations are set side by side with the operations of comparison and seeing relations. Locke holds that such operations are not present in animals. The complex ideas of animals are apparently combinations of simple ideas given to, not made by, the animal. "They take in and retain together several combinations of simple ideas, as possibly the shape, smell and voice of his master make up the complex idea a dog has of him, or rather are so many distinct marks whereby he knows him; yet I do not think they do of themselves ever compound them, and make complex ideas" (II. xi. 7). These operations of mind in building complex ideas are never brought into clear relation with the operation which constitutes knowledge—namely, "perception of the connection of and agreement, or disagreement and repugnancy, of any of our ideas". Cutting across his attempted psychological account of how complex ideas come to be formed, Locke gives a logical classification of complex ideas according to the nature of their object or reference: there are ideas of modes, of substances, and of relations. In this we have another example of the confusion of the psychological and the logical point of view, or shall one say of transition from one to the other without any realisation of the change in outlook?

No orthodox psychologist from the time of Wundt onward would have admitted for a moment that his acceptance of sensations as psychological simple elements was due to logical analysis. He would have declared that it was due rather to the analysis of physiological events, namely, the simple stimulation of a sensory receptor and the resultant excitation of the central nervous system.

I question whether any psychologist who sets out from simple sensations is really determined by a search for what is primitive in experience. That we do not experience simple sensations as such is, of course, admitted on all hands; when treated as elements they are often said to be reached by 'hypothetical' analysis. What I want to suggest is that such analysis is the outcome of logic, not psychology. The method implies that perceptual knowledge is a structure, the logical analysis of which will yield the bricks out of which it is made. This is a teaching derived from Locke's Essay. The use to which the Association school put Locke's theory of association rests on this doctrine. The theory is given in a section added to the fourth edition of the Essay, and was put forward as a theory to explain strange aversions and likings, prejudices and errors. It is never put on a level with the synthetic processes of knowledge wherein there is perception of a relationship between ideas. Association is thus primarily a way of uniting items which are discrete and have no intrinsic connexion with one another.

Gestalt psychology to-day is never tired of proclaiming itself as a revolt from associationism. Even if we believe that associationism in pure psychology is dead, how far may it, nevertheless, be true that *Gestalt* is fighting a present-day attitude of mind which had its historical foundation in Locke's confusion of logical analysis with an inquiry into psychological genesis?

Gestalt psychology would claim that no constructive explanation can be satisfactory which sets out from such elements as sensory events or reflex responses, and attempts to build up the experienced phenomena of human awareness and behaviour by the synthetic method. Perceptual awareness of a situation and responsive behaviour must, on its view, be taken *in toto*. The explanation of why just 'this' is perceived rather than 'that', must be sought in the physical constitution of the immediate environment and in the total condition of the organism. The school sets itself the task of studying the conditions in the stimulating situation which determine the perception of this pattern rather than that. It is always the pattern or configuration as a whole which has to be explained. Much experimental work has been done and valuable information obtained, particularly in the field of visual perception.

Whereas for the 'orthodox' school—if there is still a school capable of claiming this adjective—'meaning' in the form of memory images, actual or potential, comes in as an ingredient in the complex perception of an x, for *Gestalt*, meaning may lie in the nature of the sensory pattern or total organisation. To take an example, size or shape perceived in indirect vision is not 'apparent' size or shape modified by the memory of 'real' size and shape; the size or shape actually perceived is due to the sensory pattern of the whole field.

It is 'organisation' which for *Gestalt* replaces the conception of association. The so-called association of contiguity is never mere collocation in time or space. It is always an instance of organisation. "Organisation is not at all an aggregation of indifferent material. . . . If association is a consequence of organisation, it must also depend upon the mutually relative properties of what is or shall be organisated" (Köhler, "Gestalt Psychology", p. 211).

When we turn to the question, How do organisations arise ? we may not be wholly satisfied with the answers at present forthcoming. There are the sensory organisations or patterns the conditions of which are being experimentally investigated. Here the relative importance of the environmental and the intra-organic factors stands in need of elucidation. Descriptive terms such as 'closure', 'nearness', 'pregnancy', 'symmetry' summarise the present formulations of experimental findings. There are also the organisations said to be created intentionally. Here the 'self' and 'attitudes' are called in as explanatory concepts, and with them we pass over into a speculative region of tensions and dynamic relations in the brain field, a somewhat misty region in our present state of knowledge.

The contemporary representatives of Locke's doctrine of association are the behaviourists. According to this school, man is born with certain native responses to definite conditions in his environment: his unconditioned reflexes. He 'learns' or acquires new responses when an original response is extended to a different situation or when an original situation is made to evoke a different response.

This acquirement is the result of 'conditioning'. All conditioning depends upon the temporal arrangement of the factors in the stimulating situation and upon the structure of the animal's nervous system. Conditioning is a scientific formulation of the facts noticed by Locke as association. "Custom settles habits of thinking in the understanding, as well as of determining in the will, and of motions in the body: all which seems to be but trains of motions in the animal spirits, which, once set agoing, continue in the same steps they have been used to; which, by often treading, are worn into a smooth path, and the motion in it becomes easy, and as it were natural . . . and are therefore called so, *though at first they had no other original but the accidental connexion of two ideas*, which either the strength of the first impression, or future indulgence so united, that they always kept company together in that man's mind as if they were but one idea" (Essay, II., xxxiii., §§ 6 and 7). In the language of behaviourism, such a man is 'conditioned' to respond to the second idea as he originally did to the first. As in associationism the complex phenomena of mind were constructed from the simple ones by association, so in behaviourism all the complex phenomena of human behaviour are constructed from the simple units of reflex responses by conditioning. Behaviourism presents us with a tidy system wherein everything hangs together. The whole of man's thought (speech) and conduct is theoretically capable of being explained deductively from his original reflexes subject to conditioning.

There are other contemporary schools wherein association figures as a great principle of linkage, but in each of them some condition over and above bare sequence is recognised. In the psychology of Prof. McDougall, association by bare contiguity has a place, but he also lays great stress on the learning that implies a thread of purposive interest. The *a*, *b*, and *c* that are associated together are members of what Prof. Stout terms a 'conative unity'. This interest would be an essential feature in the experience acquired in working out any instinctive tendency. Membership of a purposive whole is in principle a radical departure from association by temporal contiguity.

In psycho-analysis there is again great emphasis on association and its opposite, dissociation. The old forms of association, contiguity and similarity, are retained, and much use is made of them in explaining transference, trains of ideas, complexes, but the operation of association links appears to be completely controlled by instinctive and emotional dispositions. The machinery of association is the same as in the older doctrines, but the levers are operated by forces which lie quite outside the ken of association psychology.

Association figures also in the motor theory of consciousness, and here it would seem to be more after the old pattern. All association is between movement systems. Contiguity and similarity must be interpreted as contiguity and similarity between the systems of incipient and overt movements involved in the associated ideas.

We have said that Locke left his afterthought, his union of ideas by association, unreconciled with, or unrelated to, his account of knowing. Knowledge is the perception of the connexion of and agreement, or disagreement and repugnancy, of any of our ideas. In Book IV. he gives us a classification of the kinds of connexions and repugnancies we thus perceive: identity, relation, co-existence or necessary connexion, real existence. It would be out of place to go into the details of each class. What is at once apparent is that in all varieties of knowing the knower is perceiving some kind of relation between his ideas. They are synthesised or united in virtue of a perceived agreement or repugnancy.

If we turn to contemporary psychology, we may compare this doctrine with the principles of cognition laid down by Prof. Spearman. Prof. Spearman calls his qualitative principles of cognition 'noegenetic'. He claims that they and they alone are generative of new items in the field of cognition. Familiar as these principles may be, I will venture to quote the second and the third. The second is the principle of the eduction of relations: "The mentally presenting of any two or more characters (simple or complex) tends to evoke immediately a knowing of relation between them". The third is the principle of the eduction of correlates: "The presenting of any character together with any relation tends to evoke immediately a knowing of the correlate character". These two principles make the knowing of relations the basic fact of cognition. They are the key to intelligence.

Prof. Spearman would agree with *Gestalt* psychologists in stressing organisation. He differs from them by regarding organisation as dependent upon perceiving characters as related. All organisation or synthesis depends ultimately upon cognised relations. He thus denies sensory organisations as

simple data. By his second principle he necessarily repudiates association in the Lockian sense. Although he keeps the names of the old laws of association, contiguity and similarity, he states explicitly that "quasi-mechanical reproductive adherence has its source in the noetic coherence". In principle, reproduction by association and the eduction of correlates are akin. The distinction is that in reproduction the relata have already been related in past experience, the organisation is old, whereas in eduction of correlates the educed correlate is new. It is this aspect of his third principle in creating new knowledge that Prof. Spearman wishes to stress, and it is just this stress that differentiates his principle from that of relative suggestion advocated by Thomas Brown in his "Philosophy of the Human Mind", 1820. Whether such a distinction of 'old' and 'new' is one that can be drawn in any absolute sense is a question that need not be raised in this connexion.

Locke left us with unreconciled methods and principles, and in connecting these with differing schools in contemporary psychology, I may seem to be emphasising divergencies of doctrine. Indeed, I may seem to be giving support to the gibe that to-day there is no psychology, only a collection of psychologies. By many this is thought to be a sure sign of decadence. At first sight there is much in the present situation which may give rise to a sense of disappointment to those of us who belong to the older generation. The present century opened full of hope—psychology was emerging as a new science. It was being recognised as something distinct both from philosophy and from physiology. It was rapidly developing a technique of its own. All was 'set fair' for the growth of the 'new' psychology. It is true there were schools in a very limited sense. There was Leipzig, Göttingen, Paris, Harvard, Cornell, etc., but the lines of cleavage represented, say, at the Paris Congress of 1900, were but deep furrows in a common experimental field. To-day the schools appear to be separated by unbridged gulfs. Yet it is little more than fifty years since Wundt opened his laboratory in Leipzig, and fifty years is a brief interval in historical retrospect.

Is the present division of theory really a bad sign? Does it indicate the 'petering out' of the spirit which animated the workers from 1879 to 1900, or is it a sign of vigour? I believe there are good grounds for believing the latter alternative. Prof. Woodworth, in his book "Contemporary Schools of Psychology", declares, "all the schools are emphasising something that demands emphasis and serve a useful function in the progress of psychology". The methods and principles which find a place in Locke's Essay may demand for their reconciliation, not resolution but increase of knowledge, to enable us to mark out their respective spheres.

If Prof. Woodworth is right, we need reject no 'psychology' as false, but rather consider how far its particular teaching serves to explain certain aspects of complex human phenomena. This thesis can be illustrated by applying it to the data of experiments on recall.

Obituary

Mr. E. Edser

Many students of physics, as well as numerous friends in the world of applied science, will regret to learn that Mr. Edwin Edser died on Aug. 17, at sixty-six years of age, after a long period of acute suffering bravely borne. He was one of the most unassuming of men, yet everyone who knew him appreciated the breadth and depth of his knowledge of all branches of physics, and his clear understanding of fundamental principles used either in theory or in practice.

Mr. Edser was a student at the Royal College of Science, South Kensington, and obtained his associateship in physics in 1892, being top of the list. After a year of research he was appointed demonstrator in physics at the College, under Sir Arthur Rücker, and in 1895 became lecturer in physics and head of the mathematical department of the South-Western Polytechnic, Chelsea. Later, he was lecturer in physics at Woolwich Polytechnic, and from 1903 until 1914 was head of the Department of Physics at Goldsmiths' College, University of London.

While at the Royal College of Science, Mr. Edser carried out some notable pieces of research and was associated with Sir Arthur Rücker in an important paper on the objective reality of combination tones, read before the Physical Society in March 1895. The question of the objective existence of summation tones as distinguished from supposed beat tones, which had previously been the subject of much controversy, was proved conclusively by the experiments and results described in this paper.

Mr. Edser was an ingenious experimenter, and so long ago as Aug. 17, 1893, he contributed an article to Nature upon a simple arrangement of apparatus devised by him to illustrate Michelson's method of obtaining interference bands. The use of this apparatus in connexion with experiments on change of phase of light after reflection at a silver surface was described by him in an article in Nature of Sept. 23, 1897. Mr. Edser was probably one of the earliest experimenters in Great Britain to make use of the principle of Michelson's interferometer, and he applied it to investigate the effect of movement in liquids upon the velocity of light. He also used the instrument in an investigation with Mr. S. G. Starling on the effect of the electric discharge upon the velocity of light. In a paper read before the Royal Society in 1898, Mr. Edser developed Maxwell's electromagnetic theory of light so as to include dispersion, metallic reflection, and allied phenomena.

In a letter to Nature of May 2, 1912, concerning peculiar shadows cast by leaves during the partial solar eclipse of April 17, 1912, Mr. Edser made the

interesting observation that where a leaf was isolated from the bulk of the foliage, its shadow took the form of a crescent, thus actually being a negative image of the visible portion of the sun during its partial eclipse. In his inimitable way, he immediately devised a laboratory experiment to illustrate the phenomenon, and thus showed that when light from an extended source throws the shadow of a small object on a screen, under such conditions that the umbra of the shadow is not formed, then the shadow is the negative inverted image of the source of light.

Mr. Edser's textbooks on heat, light, and general physics are very widely known. He took special pains to make all his explanations as clear as possible, and many of the experiments described in his books were original and required only the simplest apparatus. When his textbooks were written, few science students of the standard for which they were intended were familiar with advanced mathematical methods, so the calculus was not used in them, and therefore some of the proofs now appear cumbrous from a more modern point of view. He was, however, very successful in presenting difficult parts of his subjects without making large demands upon the mathematical knowledge of students, though he was himself a good mathematician.

Since 1915 Mr. Edser's work was mainly concerned with the physical problems involved in flotation processes of mineral separation. One of his colleagues of Minerals Separation, Ltd., writes as follows:—"Much of his work in the investigation of the complex phenomena of flotation was published in the 'Reports on Colloid Chemistry' of the British Association, his more important contributions being 'The Concentration of Minerals by Flotation' (Fourth Report, Coll. Chem., Brit. Assoc. Rept., 1922) and 'Molecular Attraction and the Properties of Liquids' (*ibid.*). From the latter the following conclusions he arrived at may be quoted: 'Of the energy which represents the surface tension of a liquid 94% is located in the surface layer one molecule diameter in thickness, while the remainder is located at a greater distance from the surface'. And in respect of the Law of Molecular Attraction: 'Two molecules attract each other with a force that varies inversely as a power of the distance separating them, and this power must be higher than the fifth. In all liquids the result of analysing the experimental data is to indicate that the molecules attract each other inversely as the *eighth* power of the distance separating them, but mercury is not in good agreement with this law.' Some could have wished a wider audience for these papers than their present (virtual) burial place affords."

In several respects, Mr. Edser represented the best type of product of the physical laboratories of the Royal College of Science and the stimulating influence of Sir Arthur Rücker and Prof. C. V. Boys. He was not only fertile in ideas, but also skilful in all laboratory arts, and able therefore to devise and construct simple and effective apparatus to test or demonstrate them. Withal he was a delightful companion, an artist of considerable merit, and of catholic literary taste; and his memory will long be cherished with affection by a wide circle of friends.

News and Views

Report of Council of the British Association

THE report of the Council of the British Association, adopted by the General Committee at the York meeting, included several matters of particular interest. The period of the presidency, for example, now coincides with the calendar year instead of extending from one meeting to the next. The nomination of the new president is made known, however, on the first day of the annual meeting, and the General Committee accepted the recommendation of the Council that Sir Frederick Gowland Hopkins, president of the Royal Society, should be the president of the Association next year, when the meeting will be held at Leicester on Sept. 6–13. A notable change of policy with regard to allocations of grants to research committees was brought before the General Committee. For many years these grants have been made on a year-to-year consideration of available balances and have amounted to about £1000 annually. The general treasurer, Sir Josiah Stamp, in a memorandum upon the financial position and outlook of the Association, pointed out the weakness of this system and suggested that, for a time at least, not more than £400 should be expended annually from general funds on grants for research, and that an annual sum of £500 should be placed to a contingency fund. This recommendation was approved by the Council, which is of opinion that the true function of the Association, in making grants to research committees, is the initiation of particular pieces of research rather than their quasi-permanent endowment. In addition to the grants made from general funds at the annual meetings, the Council can deal at any time with applications for grants from the Caird Fund. Prof. J. L. Myres retires from the office of general secretary of the Association, which he has held since 1919, and the Council records its deep sense of gratitude for his devoted services. The two general secretaries are now Prof. P. G. H. Boswell and Prof. F. J. M. Stratton. The new members of Council are Sir Henry Dale, Dr. Allan Ferguson, Prof. R. B. Forrester, Dr. H. S. Harrison, Sir John Russell, and Prof. F. E. Weiss.

Social Consequences of Scientific Discovery

THE concern for the social consequences of the application of scientific discoveries which has been voiced by Dr. L. P. Jacks in a series of recent articles was reflected in several of the addresses and discussions at the recent British Association meetings. Dr. Jacks suggests that, instead of lending itself to the creation of endless desires, science might regard its task of giving man control over the forces of Nature as sufficiently advanced for the time being and turn its attention to the equally important task of assisting man to control himself. Recognition of this necessity was as explicit

in Sir Alfred Ewing's presidential address before the British Association as in the forceful address delivered by Prof. Miles Walker to Section G (Engineering), which referred frankly to the hampering of developments by vested interests and the middleman, as well as to the value of the contribution to the improvement of the lot of mankind made by those who possess the power of devoting their whole energy to the execution of sound, practical, and beneficent projects for the sake of those projects themselves and not primarily from selfish motives or in pursuance of some irrational prejudice. Long after science has shown the way to make things better for the people, unintelligent control and stupid prejudice preserve the old evils and prevent the spread of better ways. If effective action is to be taken, now that in so many fields physical science has instructed man how to control and eliminate waste, the human sciences must show him how to control the waste forces of his own nature.

As an example of the potentialities, Dr. Jacks and Prof. Miles Walker both refer to Lord Baden-Powell's discovery of how the play-hunger of the young human animal, his love of adventure and fun, his sporting instincts, and even his devilries, can be used by skilful hands for the development of self-control, self-respect, courage, loyalty, discipline, good fellowship, responsibility, and competence. This is a great discovery, to be ranked with any of the achievements of physical science, and is a token of what may be possible when we really address ourselves to the development of the social sciences. The picture Prof. Miles Walker draws of the State as controlled by the engineer, with the elimination of waste at its source, the control of production, improvement of distribution so as to secure the manufacture of things men want and their distribution in the simplest way with the minimum addition to the cost, involves drastic curtailment of competition and perhaps a profound change in our social habits and attitude towards buying and selling. In insisting on technical knowledge and administrative ability as a qualification for public office, he is, however, expounding a doctrine freely voiced in NATURE for many years, and the proposed experiment of a small, relatively self-supporting community is one that should not be without appeal to scientific workers. The time is opportune for courageous and adventurous experiment. The world has yet to receive an object-lesson in the high standard of life which should be possible by good organisation and modern methods, where prejudice and incompetence are no longer allowed to deny to society the benefits of leisure or material possessions with which the application of scientific discoveries would endow them.

Political Economy and Unemployment

THE confusion which exists in many minds between creative science and mechanical science is apt to obscure the contribution which creative science makes towards the solution of the unemployment problem, a contribution which, under modern conditions, is the more important because so many of the new industries, which fundamental scientific discoveries have created, minister to the increasing leisure needs of mankind. The escape of output from limitations of human effort, resulting from power production, has economic consequences which are already so far-reaching that, in the physical sphere, creative science can do little more than mitigate the severity of unemployment, and Mr. H. R. Leech, of 10 Dale Street, Runcorn, has rightly directed our attention to the necessity for original and creative research in that most uncreative of sciences—political economy. It is only as political economy and all the related so-called human sciences are placed on a firm scientific foundation, and as scientific methods are rigorously applied to the analysis of the problems of distribution of leisure and goods with which we are confronted in the age of incredible abundance which science has given us, that we can expect to solve an unemployment problem of the present magnitude. When impartial solutions have been mapped out by scientific methods, there will still remain for scientific workers and others the moral responsibility of seeing that those solutions are applied, and that the profusion with which science has now endowed mankind is no longer permitted to exist side by side with such widespread unemployment, poverty, and distress.

Scientific Research and Industry

THE Committee appointed in March 1931 by the Economic Advisory Council to examine the project for promoting new industrial development in Great Britain by establishing a central national research organisation independent of existing Government and private organisations, has just issued its report. This gives a survey of the existing organisation of industrial research in Great Britain and an analysis of the arguments for a new national research organisation, as well as of proposals for a development fund for the Department of Scientific and Industrial Research, a compulsory levy for support of research associations, and the preparation by Government of scientific digests. The Committee is satisfied that the existing Government organisation for the promotion of industrial research is efficient and sufficiently flexible to enable it to develop along the lines required to meet the changing needs of industry. The formation of a new national research organisation would cut right across the existing organisation of the Department of Scientific and Industrial Research, and, by causing confusion of purpose and distraction of effort, would be likely to injure rather than forward the cause of scientific research in British industry.

Research Development Fund

THE Committee considers it is highly desirable that the Government should have at its disposal a small fund for research development, and that provision should be made for its continuance when the balance of the fund at the disposal of the Advisory Council for Scientific and Industrial Research is surrendered to the Exchequer at the end of the current year. The Committee refers to evidence received as to the value of the services rendered to industry by the research associations, and trusts that it will be possible for the Government to continue to provide sufficient financial assistance to secure their efficient functioning until industry

is in a position to bear the whole of their cost. At the same time it is considered that if an industry can produce a practicable scheme, Government assistance in obtaining Parliamentary powers for a compulsory levy should be forthcoming. We hope to discuss this Report in more detail in due course.

Liebig and Faraday at York

It is one of the benefits of international intercourse that visitors to a country often record in their letters and diaries their impressions and memories of men and institutions, for which we cannot be too grateful. From these records we get those glimpses of the past which often escape the historian. Thus from the memoirs of Bishop Taylor of Norwich we can picture the aged Haüy—who looked like a man picked out of a crystal—lecturing at the Jardin des Plantes, where, "as everywhere also, the utmost liberty is shown to all, but to Englishmen particularly your country is your passport"; while from the letters of Helmholtz we see Tait "a particular form of savage" at St. Andrews, where, devoted to golf, he could only be brought to talk of rational matters on a Sunday. Of all the men of science who visited England in the early days of Victoria, none was better known than Liebig, who was at York for the 1844 meeting of the British Association, and afterwards toured Great Britain in the company of Playfair, Daubeny, and Dean Buckland. After his return to Giessen, Liebig wrote a charming letter to Faraday, which was long treasured by the late George B. Buckton, and which through the kindness of Miss A. M. Buckton was published in full in the *Times* on Aug. 31. During this year's meeting of the British Association the letter has been on exhibition, and Miss Buckton proposes to send it to General Smuts, as a contribution to the newly built Witwatersrand Library. It is stated in the *Times* that the letter has hitherto been unpublished, but perhaps it should be pointed out that it was printed in W. A. Shenstone's "Justus von Liebig, his Life and Work", published by Messrs. Cassell and Co. in 1901. While Liebig's letter contains an interesting view of British science at the time, Frank Buckland has left us an equally interesting contemporary account of the happy surroundings in which Liebig lived and worked at Giessen.

Founders of the Royal College of Chemistry

The memory of Liebig is also revived by an article, accompanied by a reproduction of a daguerreotype of five of his assistants, contemporaries in his laboratory at the University of Giessen, all of whom were pioneers of chemistry, which appears in the *Times* of Sept. 5. Three were German—Hofmann, Fresenius, and Will—and two were English—Gardner and Bullock, who were associated in 1845 in the foundation of the Royal College of Chemistry, of which Dr. Gardner was secretary and Hofmann the first professor of chemistry. That three of the chemists associated with the Royal College of Chemistry in its early days should be included in a single photograph will be of special interest to past and present students of the Royal College of Science, its lineal descendant. "Ninety years ago", says the writer of the article, explaining the picture, "five young men met for a solemn function. . . . They met to be photographed." He gives a list of the distinguished chemists trained by Hofmann at the College, of whom Prof. H. E. Armstrong survives.

The Chinese Earthquake of Aug. 14

An earthquake of considerable severity occurred in the south-west of China at about noon (Chinese time) on Aug. 14, and was registered by seismographs throughout the world. From the records at six observatories, the officials of the U.S. Coast and Geodetic Survey place the epicentre in about lat. 27° N., long. 103° E. (Wire Report of Science Service, Washington, D.C., Aug. 16). This point lies near the northern boundary of the province of Yunnan, about seven hundred miles to the south of the province of Kansu, in which the destructive earthquakes of 1920 and 1927 occurred. Kansu is a thickly populated province, and it is possible that some thousands of lives may have been lost, though weeks may elapse before news reaches us from the central district. From the beginning of the sixteenth century, it has been visited by twenty disastrous earthquakes, by one of the latest of which, in 1888, about five thousand persons were killed. According to Mr. N. F. Drake (*Amer. Seis. Soc. Bull.*, vol. 2, pp. 40-91; 1912), the province of Yunnan is one of the most important earthquake districts of China. He represents the relative seismicities of the four principal districts—Fukien, Kansu, Chihli, and Yunnan—by the numbers 100, 98, 94, and 91.

The Rubber Industry in Malaya

The rubber industry of Malaya is passing through the most critical period which it has yet experienced, so that the issue of a special rubber number of the *Malayan Agricultural Journal* (vol. 20, part 5) is of particular interest. The recent decision against compulsory restriction of rubber growing, though a disappointment to many, has, by removing the element of uncertainty, enabled the estates to frame their policy more clearly. Under-consumption rather than over-production is the cause of the present crisis, so that it is hoped to rectify matters by more intensive production on areas actually in tapping, and by improving the liaison between the scientific investigator and both producer and consumer. Already great reductions have been effected in the cost of production. Factory improvements, such as the construction and installation of batteries of light sheeting machines in cascade or file formation instead of in line, have facilitated and accelerated the handling of the coagulum, and more rapid methods of drying and smoking have been evolved. Economy has also resulted by the use of treated hessian for packing in place of the usual wooden chests. Considerable increase in the export of latex continues, and the extended application of this form of product to new uses is a hopeful sign of development on at least one side of the industry. Every effort is being made to study the best methods for growing and manuring the crop and for controlling the various diseases and insect pests which attack the rubber plant, so that when the industry

emerges from its present difficulties it seems reasonable to believe that a standard of efficiency of production will have been achieved such as was undreamt of in the prosperous time which formerly prevailed.

Briquette Method of Reafforestation

A SOMEWHAT novel method of sowing tree seeds is alluded to by Prof. Svend Heiberg, of the Department of Sylviculture of the New York State College of Forestry at Syracuse, in a Science Service Bulletin, dated June 29. Prof. Heiberg has been studying forestry methods in Europe, and was interested in a new type of seed-sowing developed in Norway which he terms " planting forests by the brick instead of by the tree ". The seed bricks or briquettes are made of good soil and are $1\frac{1}{2}$ in. × $1\frac{1}{2}$ in. in size. Three or four seeds are placed at one end, near the surface. The briquette is then dipped in paraffin wax, except the side in which the seeds have been placed. The result is an easily transported product, which can be placed in the ground by means of a special tool designed for the purpose. A machine can turn out 16,000 briquettes in a day. Prof. Heiberg suggests that the idle lands of the United States may be reafforested by planting briquettes instead of trees. He has been experimenting with this new system of planting or sowing at the College, but has not yet had time to decide upon its successful possibilities. He realises that the method would only be practicable on bare land free of heavy weed growth. In the absence of any figures of cost and of data of success achieved, it is not possible to compare the cost of the method with ordinary broadcasting or patch sowing; but Prof. Heiberg is probably correct to a point in stating that " In the reafforestation of comparatively clear fields the briquette system will do away with tree nurseries. It has other important advantages. It permits the root system to develop normally and also avoids disturbance of the roots at the time of planting "—though these latter apply to all tree seed-sowing.

Tuberculosis in Cattle

THE eradication of tuberculosis from cattle herds is the subject of a recent article by James Mackintosh (*J. Roy. Agric. Soc.*, vol. 92), who, besides describing the steps already taken in England and other countries to reduce the incidence of this disease, offers some practical recommendations as to how it may be more effectively stamped out. Although eradication by means of vaccines designed to confer immunity is still in the experimental stage, the testing and separating of reactors from non-reactors has met with success in northern European countries and seems to be the most hopeful method for adoption in Great Britain. Greater uniformity is, however, desirable in the application and interpretation of these tests. The measures taken under the Tuberculosis Order, 1925, to destroy all animals suffering from 'open' tuberculosis having failed to attain their object in time to be of real value, amplification of the order is recommended so as to ensure a general systematic inspection of cattle, by means of which tubercle-free beef and dairy herds may be built up, with a possible development in the future of definite 'accredited' areas. In this respect the Milk (Special Designations) Order has been of definite use by providing the only official recognition in Great Britain for herds which have been tested and contain no reactors. The practicability of such a scheme as that issued by the National Veterinary Medical Association is made evident, and the cost, if shared by the State, the local authorities, and the farmer, should not be heavy, whereas the benefit to the cattle industry and the community in general would be very considerable.

Cockles of the Thames Estuary

IN the *Southend Standard* for Aug. 4 and 11, Mr. Laurence Wells describes the local cockle industry, and has collected much valuable information (" The Cockle Industry of Leigh." Part I., " Early Use of the Cockle as Food and the Rise of the Industry at Leigh-on-Sea ". Part II., " Natural History, Distribution, and Economics "). The natural knowledge of the fisherman is extensive. From experience and from observation he has acquired an intimacy with the ways of the cockle which would put many a naturalist to shame. Spawning time, free-swimming larvæ and the effects of the weather on them, their growing stages, and the strange sounds made by the young under the sand are all known to them. To the different parts of the animal he gives special names. He knows that if conditions are unfavourable the cockles may migrate to more pleasant surroundings. Cockles have been collected at Leigh for more than 150 years. To-day the industry is thriving and affords work for a number of men and women. The sand-banks and flats of the Thames estuary afford a habitat admirably suited to the needs of these bivalves, from Shoebury Sands for the whole length of the Maplin and Foulness Sands, known collectively as the " Maplins ". The Leigh men also work along the Kent side as far as the Whitstable Flats; for 60,000 cwt. of cockles, minus the shells, are demanded from them annually, valued at £11,000. The boats are of a special design and peculiar to Leigh. The cockles are collected with a special rake and are cooked, according to law, in a steam oven, before being sent to market. Apart from the sale of the cockles themselves, there is a thriving industry in by-products from the shells. A complete account of the cockle, both historical and biological, is given in Mr. Wells's interesting article.

Electric Power and Village Industries

THE 'Sofina' (Société Financière de Transports et d'Entreprises Industrielles) controls a large number of industrial undertakings in all parts of the world. In its third annual report, interesting data are given of the rapid increase in the rate of the substitution of small electric motors in place of hand power in certain districts in France. In the St. Etienne district, for example, the small workshops have increased more than fifty times during the last seven years. The number of looms in 1925 was 214, but it has now increased to more than 11,000. In the Roanne district, the number of family weaving workshops has trebled in nine years. Home workshops for machining cycle parts have increased greatly all over France. It is pointed out that this substitution has enabled the

family workshop to compete against the large factory. In the Jura department, communal workshops have placed four hundred electric lathes at the disposal of the woodworkers. This utilisation of electric power by cottages has an effect in keeping the country dwellers from drifting to the larger cities, and thus mitigates some of the social problems which many nations are finding so difficult at the present time. In Great Britain, the transmission system—the grid—will soon supply cheap electric power to several country districts. In these districts it will be possible to establish suitable village industries on a commercial basis. In time this should have the effect of easing the economic crisis. Probably training schools for craftsmanship will have to be established. If electric power is sufficiently cheap, small electric motors should enable the weaving industries to flourish in villages.

Studies of Geophysical Methods, 1928 and 1929

The Geological Survey of the Canadian Department of Mines has published, as *Memoir* 165 (Ottawa, pp. 225; 1931. 45 cents), a valuable account, under the above title, of an impartial investigation of various methods of geophysical prospecting. Electrical methods were applied in 1928 to the Abana mines property, Quebec, by generous permission of the owning company, and three electrical prospecting companies accepted an invitation from the Geological Survey to demonstrate their methods on this comparatively suitable deposit; the work was done at their own expense, under the observation of officers, both physical and geological, of the Survey. The geological, electric, and magnetic surveys showed that the physical conditions existing in the Abana mineral deposits are complex, but that, nevertheless, the magnetic and electric methods of prospecting, when used intelligently, are feasible and productive of valuable results. The work in any new area must still be to a large extent an original research, requiring the use of highly trained and skilled men. Further work on the Abana property, and elsewhere, was done in 1929, partly in co-operation with the U.S. Bureau of Mines and (in gravity work) with the Dominion Observatory of Canada. At the Errington Mine, Ontario, an area was met "for the first time" where, in the present state of our knowledge, geophysical methods were of small avail, and where the diamond drill under the direction of geologists and mining engineers was the sole guide to further discovery.

Actinometric Bibliography

The Association of Meteorology of the International Union for Geodesy and Geophysics, at its Stockholm meeting in 1930, gave a subvention for the preparation of a bibliography, or rather a series of short abstracts, of papers on actinometry. These are prepared under the supervision of M. Wehrlé, secretary of the Association, at the French National Meteorological Office, by M. Volochine; where possible, the abstract is provided by the author, and English, French, and German versions of the abstracts are available, at the choice of subscribers. Each abstract is on a single leaflet, of convenient size for binding; the leaflets are well reproduced by lithography from typescript. The normal annual number of leaflets will be 300-400, but the bibliography is to be retrospective, covering the last thirty years; this work, involving about 2000 leaflets, being planned to occupy about two years. The leaflets are to be sent to subscribers in packets of fifty. Subscriptions are invited, though the amount of subscription will not be fixed until the demand for the leaflets is ascertained; it is expected, however, to be about 120 francs per year (for 400 leaflets), and 600 francs for the retrospective bibliography (for 2000 leaflets). Intending subscribers should write to M. Wehrlé, at l'Office Nationale Météorologique, Paris.

Turquoise Mosaic Plaque from Chichen Itza

A mosaic plaque of turquoise and jade, it is announced by Science Service, of Washington, D.C., has been discovered under the Castillo mound, in the ruined city of Chichen Itza, Yucatan. This announcement recalls the discovery, also at Chichen Itza, of a similar plaque—one of the most remarkable objects of the art of the ancient Mayas ever found—which was made in 1928 by an expedition sent out by the Carnegie Institution of Washington. This plaque was made of turquoise mosaic on a foundation of wood, which had perished. The services of a museum expert were requisitioned from New York for its removal. The operation of salvage, which necessitated the improvisation of a special technique on the spot, took three months to complete. The plaque was exhibited for the first time at the International Congress of Americanists which met in New York in September 1928. The plaque which has recently been found is described as a mosaic of turquoise and jade, and, like the preceding find, is on a foundation of wood, now decomposed. It lies in a stone box under a number of fragile articles not yet removed. The tomb under the mound appears to be a secondary burial, and turquoise spearheads may indicate that the occupant was a warrior.

Announcements

The Alexander Pedler Lecture of the British Science Guild will be given this year, under the joint auspices of the Burton-on-Trent Natural History and Archæological Society and the Guild, at Burton-on-Trent on Nov. 4, by Prof. F. T. G. Hobday, principal and dean of the Royal Veterinary College, London. Prof. Hobday's lecture will be entitled "Animals as a National Asset and Responsibility". The Norman Lockyer Lecture of the Guild will be delivered on Nov. 22 by Sir Frank E. Smith, secretary of the Department of Scientific and Industrial Research.

Applications are invited for the following appointments, on or before the dates mentioned:—A lecturer in electrical engineering at the Leicester College of Technology—The Registrar (Sept. 12). A lecturer in physiology for education students at the University of Leeds—The Registrar (Sept. 15). A lecturer in physical chemistry at Auckland University College, University of New Zealand—The Secretary of the Universities Bureau of the British Empire, 88a Gower Street, W.C.1 (Oct. 10). An assistant bacteriologist at the Royal Institute of Public Health—The Secretary, 23 Queen Square, W.C.1.

Letters to the Editor

Altitudes to be Reached by Air Pilots by Breathing Oxygen

SCHROTTER (1904)[1] gives the following figures:

Altitude.	Pressure.	Tension of Oxygen if Pure Oxygen were breathed.
11,000 m.	190 mm. Hg.	25 per cent of an atmosphere.
14,500	127	16·6
17,000	93	12·5
20,000	76	10

At normal atmospheric pressure, most people can bear a reduction of oxygen from 21 to 12·5 per cent of an atmosphere without distress, but if the tension of water vapour in the lungs is, as assumed by Schrotter, 47 mm. of mercury, and that of carbon dioxide 30 mm. Hg, a total pressure of 77 mm. Hg, then at 17,000 m., where the pressure is 93 mm. Hg, the tension of oxygen, even when pure oxygen is breathed, must be far too low to support life, namely, $93 - 77 = 16$ mm. Hg. Argyll Campbell found that animals could live when the tension of oxygen in the lungs fell to 50 mm. Hg, but degeneration of the heart and other organs resulted on prolonged exposure to this tension, which is one-third of the normal, and corresponds to that at the top of Everest. We know how very distressed the best climbers became on reaching 28,000 feet; two lost their lives, never returning from their final effort to reach the top.

On repeatedly exposing 4 mice, 7 rats, 2 guinea-pigs, 1 rabbit, and 2 goats in chambers to oxygen (about 98 per cent) and evacuating the chambers, I found all these animals to be not distressed when kept for five minutes or more at a pressure of 100 mm. of mercury, but to be uncomfortable at 90 mm. Hg, and prostrated, or convulsed, at 85-70 mm. Hg. The experiments were carried out in special chambers and with vacuum pumps and animals (goats) kindly placed at my use by Sir Robert Davis at the works of Messrs. Siebe, Gorman and Co., Ltd.

Very conclusive evidence was obtained from the two goats. When the pressure sank to less than 100 mm. Hg, each goat licked its lips and moved a little as if uneasy; at about 90 mm. Hg each lay down; at about 84 mm. Hg a convulsive movement due to want of oxygen was apparent. All the animals recovered at once on letting in more oxygen and raising the pressure.

It is clear from these experiments that the total tension of water vapour and carbon dioxide in the lungs must be considerably lower than that assumed by Schrotter, at any rate at low atmospheric pressures. The tension may be reduced by better ventilation of the lungs. Haldane says the tension of carbon dioxide in the lungs may be halved at 35,000 ft., but he assumes the tension of water vapour to be 47 mm. Hg. This scarcely can be the case.

Schrotter put the limit of altitude attainable by air pilots with the help of breathing apparatus at 11,000 m. or a little above this figure. These animal experiments show that, given an efficient oxygen breathing apparatus and an hour, say, spent in breathing oxygen before the climb in order to wash out nitrogen from the body, a pilot might attain certainly to 50,000 and perhaps even to 55,000 ft. A pressure of 95 mm. Hg corresponds, according to Schrotter's figures, to 55,800 ft., and all the animals withstood decompression to this figure without serious signs of discomfort. It is noteworthy that Paul Bert (1878)[2] records that a sparrow decompressed in 92 per cent of oxygen fell over as if dying when the pressure was lowered to 75 mm. Hg.

The Practice of Dental Mutilation

IN NATURE of Aug. 20, p. 268, reference is made to a letter published in the August number of *Man* in which I state that the earliest evidence I could find of evulsion of teeth and other dental mutilations in Nubia could not be pushed back before about 300 B.C.

I have no reason for modifying that statement. Nevertheless, as Dr. Wilfrid Jackson reminds me in a personal letter, I overlooked the fact that there is evidence from other places to suggest that the practice of dental mutilations may be very much more ancient than the Nubian record suggests. In October 1914, Dr. Jackson published an article entitled "Dental Mutilations in Neolithic Human Remains",[1] in which he quotes evidence which seems to establish the fact that during the Neolithic period evulsion of the teeth was practised in North Lancashire and North Wales. Moreover, in this article he cites information suggesting the possibility of dental mutilations at the time of the Egyptian Middle Kingdom (about 1800 B.C.) on the basis of a skull of the twelfth dynasty in the Manchester Museum. Moreover, Dr. Douglas Derry describes a case which, so he claims, reveals dental mutilation in a late pre-dynastic skull from Lower Egypt, found by Sir Flinders Petrie. In view of this information, it is clear that I must modify the statement which I made on the basis of the Nubian evidence. The addition of fifteen (and possibly thirty) centuries to the antiquity of the practice of removing the teeth, if the somewhat sketchy data should be confirmed, will prepare the way for the elimination of certain difficulties in interpreting the evidence obtained by Miss Dorothy Garrod in the skeletons from Palestine regarded by her as mesolithic.

Dr. Wilfrid Jackson directs my attention to an article by Prof. Yoshikiyo Koganei[2] on the occurrence of dental mutilations in so-called stone-age Aino remains from the shell-mounds of Japan. I have the less excuse for forgetting this fact because two years ago, during my visit to Tokyo, Prof. Koganei showed me the actual specimens.

While none of the evidence which escaped my memory when I was writing my letter to *Man* is quite conclusive, its cumulative effect is to raise the possibility that the practice of evulsion of the teeth may be much older than I assumed to be the case.

In drawing inferences from sporadic instances of the absence of incisor teeth, the fact should never be overlooked that such deformations may easily be produced as the result of disease or accidental injuries inflicted by a process no more lethal or culturally significant than prize-fighting. In fact, it is doubtful whether the instances attributed to the Egyptian pre-dynastic period and Middle Kingdom are of any real significance as evidence of a cultural practice, and Dr. Wilfrid Jackson's Neolithic examples may possibly come into the category of accidental injuries.

G. ELLIOT SMITH.

Ionisation by Positive Ions

IN recent years many theories of discharges in gases have been proposed which do not afford a consistent explanation of the principal properties of currents obtained in gases under various conditions. According to a theory which has been much advocated,[1] it is said that atoms of the gas are not ionised by single impacts of electrons in discharges at pressures greater than that corresponding to the minimum sparking potential, since the electrons lose their energies in producing metastable atoms and therefore cannot attain the ionising potential. So far as the action of electrons is concerned, it has already been shown that this theory of collisions is inconsistent with the ordinary properties of glow discharges.[2]

Recent theories [3] also involve unsatisfactory hypotheses with regard to the action of positive ions in contributing to the conductivity.

In these theories it is maintained that atoms or molecules of a gas cannot be ionised by the collisions of positive ions unless the kinetic energy of the ions is of several thousand volts. Thus if the ionising potential of an atom be 10 volts, a hydrogen ion would require an energy of at least 4500 volts in order to ionise the atom.[4] It has therefore been concluded that in discharges where the potentials between the electrodes are less than a thousand volts, the action of the positive ions in contributing to the conductivity is limited to the liberation of electrons from the negative electrode, and in order to explain the corona discharge it was found necessary to assume that the emission of electrons from the electrode is independent of the energy of the positive ions acquired by moving under the electric force in the gas. The objections to these hypotheses as a basis of a general theory of discharges have been pointed out.[5]

The modern theories thus differ from the well-known theory of the disruptive discharge which was deduced from experiments made some years ago in the Electrical Laboratory, Oxford.

In this theory, in order to reconcile the results of the experiments on currents between parallel-plate electrodes with experiments on the corona discharges, it is assumed that molecules or atoms of the gas are ionised by the collisions of positive ions in discharges maintained by potentials of a few hundred volts, where a small proportion of the ions acquire energies of about twenty volts. When the electric force is small and the gas pressure is large, the rate of ionisation due to positive ions is very small, but it is increased when the force is increased or the pressure reduced. Thus the ionisation increases with the kinetic energy acquired by the positive ions in moving under the action of the electric force.

We have recently made direct experiments to determine the effects of positive ions in hydrogen, the apparatus being designed so that it was possible to separate the effects of the liberation of electrons from the negative electrode from the effect due to the ionisation of atoms of the gas. We find that the number of electrons generated by positive ions in a current between parallel plates depends on the electric force and on the pressure of the gas. There is a large increase in the number of electrons thus generated, corresponding to a small increase in the force with forces of the order of 100 volts per centimetre and pressures of the order of half a millimetre. Also with copper plates 2 cm. apart the number of electrons liberated from the negative electrode is small compared with the number of molecules of the gas that are ionised by the impacts of the positive ions.

These experiments show that the energies of the positive ions in the collisions in which molecules are ionised are of the same order as that of the electrons, so that the velocities of the positive ions in these collisions are of the order of one-hundredth of the velocities of the electrons.

These results therefore confirm the earlier theory of disruptive discharge, given in the treatise "Electricity in Gases".

Polarisation of Echoes from the Heaviside Layer

ONE of the most fruitful methods of investigating the Heaviside layer is that originated by Breit and Tuve, in which a series of short impulses of the order of 0·2 of a millisecond in duration are transmitted and the direct ray and echoes reflected at nearly normal incidence are observed at a neighbouring station. The echo patterns observed are often very complex and it has been found that a single *F* layer echo, say, is often split into two fairly closely spaced components. This has been attributed by Appleton to the double refraction suffered by a ray in passing through the ionised regions of the upper layer.

The double refraction is caused by the earth's magnetic field. According to the theory, these two components should be oppositely circularly or elliptically polarised. A complete proof that the splitting of echoes is due to double refraction should involve a demonstration of this fact. A recent experiment, in which this result is clearly demonstrated, constitutes a striking proof of the magneto-ionic theory of radio transmission.

For the purpose of determining the state of polarisation of the downcoming waves, two separate vertical tuned loop aerials perpendicular to each other, as in a Bellini-Tosi direction finder, were used at the receiving end. These were coupled in the usual way to a search coil which fed the receiver. The output of this actuated a cathode ray oscillograph in the normal way for demonstrating the echoes. The object is to use the double frame as a polarimeter. This can be achieved as follows: The aerial is set so that the angle between the two frames is bisected by the incoming direct or surface ray. The aerials are then tuned so that the currents in the two are in phase with the e.m.f.'s, which are also in phase. The search coil of the goniometer can then be set at 45° so as to receive no signal. The aerials are then mistuned, one being increased in natural period and the other reduced. When the e.m.f.'s in the aerials are in phase, the resultant is a rotating field in the goniometer and no position of balance can be found.

Consider a ray returned from the Kennelly-Heaviside layer: if this is circularly polarised, then the e.m.f.'s in the two frames will be 90° out of phase. If the mistuning of the aerials has been properly carried out so that the current in one is advanced 45° on the e.m.f. and retarded 45° in the other, then, when the e.m.f.'s are 90° out of phase, the currents will either be in phase or 180° out of phase, according to the direction of circular polarisation. It follows that for a circularly polarised wave a balance can be obtained with the pointer of the goniometer either at +45° or −45°, according to the direction of circular polarisation.

Let *A* and *B* in Fig. 1 represent the components of

the split echo represented on the oscillograph screen in the usual way. Then, when receiving with this polarimeter aerial, A will be enhanced and B reduced to zero and vice versa, according as the goniometer search coil is switched, say, from a $+45°$ position to a $-45°$ position, and the pulses A and B will 'see-saw' as the search coil of the goniometer is rapidly switched from $+45°$ to $-45°$.

In testing this arrangement, the expected results were immediately shown in a most striking way. The transmission was on a 60 m. wave from Writtle, near

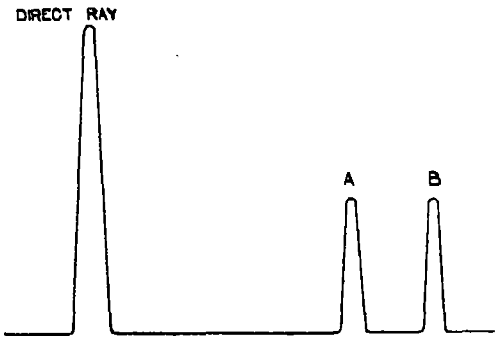

FIG. 1.

Chelmsford, to Broomfield, at a distance of 2·8 km., in which a series of pulses at a frequency of about 100 a second were sent out.

Split echoes were observed in the F layer reflections. With the aerials set up in the proper manner, switching the goniometer coil obliterated, in turn, first A and then B, producing the 'see-saw' effect expected. The results prove quite definitely that the two components are polarised in opposite directions. A knowledge of the adjustments made enables us to state that the most bent echo A is right-hand circularly polarised, looking along the ray in the direction of transmission, and the least bent echo B is left-hand circularly polarised. The arrangement enables one to examine the polarisation of each echo individually. So far as we have observed, the daytime echoes are normally right-hand circularly polarised.

This is in accordance with the view that in daytime on this wave the attenuation of the echo occurs mainly in the E layer, where according to theory the attenuation of the left-hand polarised ray should be more than twice as great as the right-hand polarised ray. This conclusion is confirmed by the observation that F_2, that is, a double reflection from the F layer, appears before the left-hand circularly polarised F_1. The arrangement should be of great help in interpreting the complex echoes that are often observed.

Evidence of a Penetrating Radiation from Thunderstorms

WE have recently carried out experiments which suggest that a penetrating radiation is emitted by charged thunderclouds. In the arrangement used, one pen of an electric chronograph was actuated by a Geiger-Müller counter, another pen by a chronometer marking half-seconds, and a third by the atmospherics received from lightning flashes on a two-valve amplifier. The records have been examined to see whether the kicks of the counter and the flashes showed any significant time relations.

It appears that, during certain distant storms, the number of coincidences between counter-kicks and flashes is considerably more than can be ascribed to chance. Analysis of the distribution of counter-kicks in time around flashes shows that the number of kicks occurring in the particular interval of $\frac{1}{100}$ sec. which is centred on a flash exceeds the chance expectation by a factor which in the case of seven different storms varied from 3·3 to 11·4. In one case in which the counter was completely shielded by 20 cm. of iron the factor was 8·0.

Precautions were taken and tests were made to exclude spurious coincidences due to the interaction of the atmospheric and the counter amplifiers with each other, or to the direct action of the atmospheric Hertzian wave upon the counter amplifier. The seven storms which gave systematic coincidences were all at distances of 30-60 km. away; overhead storms did not show them. The results thus indicate that a thunderstorm emits some form of penetrating radiation at the moment of occurrence of a lightning flash, that this is emitted upwards and not downwards, and is received at distant points by some action such as that of the earth's magnetic field upon electrified particles.

To examine whether thunderclouds can produce such radiation *before* they are discharged by lightning, we have analysed the records of 21 distant thunderstorms (3200 flashes). The number of kicks of the counter was determined in the intervals 1, 2, and 5 sec. before and after the occurrence of each flash. The storms which gave systematic coincidences also show an excess of the order of 10 per cent in the forward as compared with the backward intervals. The probable error in the total count was 3 per cent. The other storms, which did not give systematic coincidences, show no significant effect here either, for they give a forward defect of 1 per cent while the probable error in the count is 2 per cent.

The geographical distribution of the storms which showed these effects is not easy to determine with certainty since what has been referred to as a storm is actually a record of several storms in different places. What information we have on this point suggests that the effective storms lay to the east of the meridian through the station.

Observations on overhead thunderstorms provided further evidence of the screening effect on the ordinary fine weather penetrating radiation which has already been reported by one of us.[1]

The experiments were made at the University of the Witwatersrand, Johannesburg. We wish to thank Prof. H. H. Paine for many kindnesses and to acknowledge the financial assistance of the South African Research Grant Board.

Viscosity of Nitrobenzene

WITH the intention of carrying out measurements of the viscosity of liquids, we have studied recently different experimental methods, and have come to the conclusion that, for relative measurements, the oscillating disc method permits of very great accuracy. Therefore we determine first the logarithmic decrement by registering the oscillations on bromide paper. The amplitude of the deflections could afterwards be measured with no great difficulty to 0·1 mm.

It seemed to us of great interest to investigate

nitrobenzene in the temperature range from 20° down to 6° C. by this experimental method. Besides the great relative accuracy obtainable with our method, there is another advantage; during the whole of the measurements, the liquid under examination remains completely separated from the atmospheric air. So we possess a rigorous control of the purity of the nitrobenzene during the measurements. We know from recent work published by other investigators that this precaution is absolutely necessary.

A few months ago, measurements with the same object were made by Massy, Warren, and Wolfenden.[1] They used the capillary stream method. The authors mention that in spite of the precautions taken, it was quite impossible to prevent the nitrobenzene from absorbing a small quantity of water.

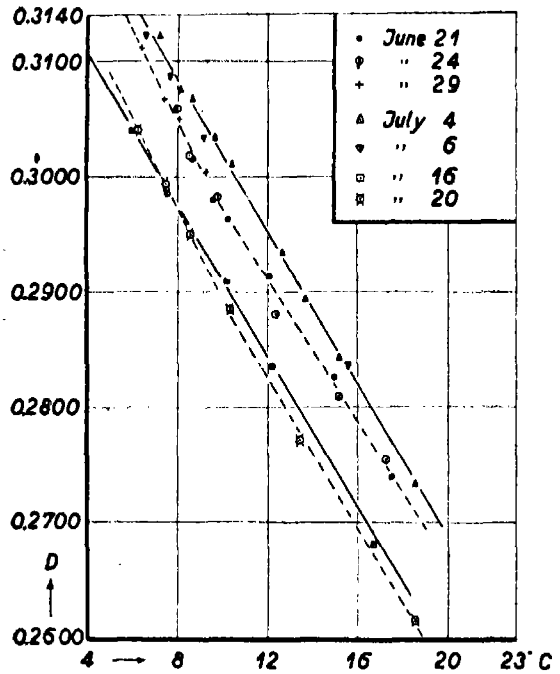

FIG. 1.

In consequence of the great accuracy of our method (0·05 per cent determined from the average error of the observations), we think it desirable to communicate our results. The experimental data are shown graphically in Fig. 1. The logarithmic decrement D has been plotted as a function of the temperature.

The measurements were made with two different oscillating systems (wire with different length). The points of the upper pair of curves correspond to the first oscillating system, those of the lower curves to the second one. Each point of the curve represents the average of about seven observations. The full lines correspond to the pure nitrobenzene,* while the broken curves correspond to nitrobenzene which was not absolutely pure and contains essentially water (m.p. 5·32° ± 0·02°).

The curve shows clearly, in both series of measurements, that for pure nitrobenzene the curves are straight lines with no discontinuous transition point. This result is in agreement with that obtained by Massy, Warren, and Wolfenden (loc. cit.), and also with the results established recently by other investigators, who measured other physical properties.

* This nitrobenzene was furnished by the Bureau Intern. d. Étalons physico-chimiques of Brussels. The melting point was guaranteed to be 5·70° (we found 5·70° ± 0·02° on a normal thermometer verified by the Physikalisch-technische Reichsanstalt).

For the impure nitrobenzene, the curves appear to be composed of two different straight lines, which cut each other in the neighbourhood of 9·6°. This experimental result agrees also with the suggestion put forward by other investigators and specially by Smits and Gerding,[2] that the phenomenon observed by Mazur[3] must be attributed to insufficient drying of the nitrobenzene, so that in the neighbourhood of 9·6° the nitrobenzene loses its absorbed water.

Finally we wish to direct attention to the parallelism between the straight lines corresponding to the pure and impure nitrobenzene. This can easily be explained since the oscillating systems differ only by the length of the suspensory wire, the rotating discs being the same.

A more detailed report about the experimental method and data will appear in *Wis- en Natuurk. Tydschr.*

Orienting Power of the Nitroso-Group and the Formula of Nitrosobenzene

THE nitroso-group in an aromatic nitroso compound appears to be chemically abnormal. Thus, in the case of nitrosobenzene, failure[1] to prepare salts or co-ordination compounds in which the nitroso-nitrogen acts as a donor atom, shows the accepted formula (1), with a tercovalent nitrogen atom, to be incorrect. Equality of the value of the dipole moment

$$C_6H_5 : \ddot{N} \vdots \dot{O}\!\!: \qquad (1) \qquad\qquad C_6H_5 : \overset{..}{\underset{\oplus}{N}} : \overset{..}{\underset{\ominus}{\underset{..}{O}}} : \qquad (2)$$

for this substance with that for nitrobenzene would indicate (2) as a possible formula, in which case the nitroso-group should be *meta*-directing in aromatic substitution reactions.

The available facts bearing on the orienting power of the nitroso-group are these: polymerisation of nitrosobenzene by sulphuric acid yielded not *meta*- but *para*-nitrosodiphenylhydroxylamine.[2] Nitrosobenzene has been *para*-nitrated[3] in carbon tetrachloride and chloroform, and *para*-chlorinated or brominated in carbon disulphide,[4] chloroform,[5] benzene,[6] and ether.[1] I suggest that all published experiments on the bromination in acetic acid solution[7] (the significant products of which have been bromoazoxybenzenes) also fall into line, because (1) these substances are not obtained from azoxybenzene and bromine under otherwise identical conditions,[1] (2) autodecomposition of mono- and dibromo-nitrosobenzenes is to be expected and should lead *inter alia* to bromoazoxybenzenes, and (3) qualitative indications have been obtained that the recovered nitrosobenzene contains traces of the *para*-bromo-derivative.[1]

Thus the nitroso-group appears to be *para*-directive, in conformity more with (1) than (2).

The nitroso-group has a strong labilising action on halogen atoms situated in the *para* position,[8] but its orienting nature cannot be inferred from this fact. Halogen activation and *meta* substitution are caused by the substituent radical in two separate ways: in the former a $-T$ effect (entirely absent during a substitution reaction) called up by the anionoid reagent, and in the latter a $-I$ effect accompanied by the

impossibility of $+T$ effects. The nitroso-group exhibits probably the strongest $-T$ effect yet recorded, but differs from nitroxyl, which can activate the halogen in *para*-halogenonitrobenzenes by virtue of the $-T$ mechanism (alkaline reagents), but which directs an entrant nitro-group into the *meta* position of nitrobenzene by reason of the permanent $-I$ effect, in that, by not possessing an ionic positive charge, $+T$ effects with the appropriate reagent will occur much more readily. *Para* substitutions take place by valency redistributions of this type occasioned by cationoid reagents; thus the direct *para* bromination and nitration of nitrosobenzene on one hand and the labilisation of bromine in *para*-bromonitrosobenzene on the other can be easily understood. The nitroso-group is unique but not anomalous.

A correct formula for this substance must, however, indicate more than (1) and (2) together show. Nitrosobenzene, like other Ar-nitroso compounds, possesses properties reminiscent of an odd electron molecule—for example, in some compounds the $-$NO group is apparently paramagnetic—and qualitatively resembles a free diarylamino-ion[8] in several respects. It thus is a case where ordinary chemical formulæ become inadequate.

A formulation involving a 3-electron bond has been implicitly stated by Pauling[9] which is satisfactory for unexcited nitrosobenzene (intermediate between (1) and (2)), which thus becomes (3)—which will, like the blue free diarylamino-radical, not only polymerise readily to a colourless dimeride (4) containing tercovalent nitrogen, but also will in different

$$\mathrm{Ph} : \overset{\cdots}{\underset{\cdots}{\mathrm{N}}} : \mathrm{O} : \qquad (3)$$

$$\begin{array}{l} \mathrm{Ph} : \ddot{\mathrm{N}} : \ddot{\mathrm{O}} : \\ \quad\;\; : \ddot{\mathrm{O}} : \ddot{\mathrm{N}} : \mathrm{Ph} \end{array} \qquad (4)$$

reactions exhibit opposite polarisations according to the requirements of the reagent. Incidentally, on these formulæ, both mono- and di-meric forms should produce *para*-substitution products, although the latter more easily than the former.

Pauling's arguments applied *mutatis mutandis* to the arsinoso-radical show that arsenic should be normally tercovalent, and that therefore no special analogy with the nitroso-group can be expected. An examination of 4-arsinosodimethylaniline has confirmed this.

Constitution of the Keratin Molecule

In dealing with my[1] comments upon their communication[2] under this title, Speakman and Hirst[3] describe as erroneous my statement that "the guanidine group of arginine does *not* . . . yield nitrogen with nitrous acid under the usual conditions". By "usual conditions" I naturally imply those generally adopted in determinations of amino-nitrogen in the course of protein analysis as described by van Slyke,[4,5] that is to say, contact between acid nitrate solution and amino-body at room temperature, for 3-5 minutes in the case of mono-amino acids and for ½-1 hour in the case of the hexone bases or proteins. Under these conditions the guanidine group of arginine is practically unaffected. The work of Plimmer[6] to which Speakman and Hirst refer is, of course, well known to me, and in that paper it is stated that any error introduced by reaction of the guanidine group of arginine in a 1-hour determination is inappreciable. With longer reaction times, correspondingly greater decomposition does occur.

In connexion with my second point concerning the importance of taking into account the amide nitrogen of wool in the calculations originally put forward by them, Speakman and Hirst have restated their case by assuming that all the arginine and lysine in wool is combined with glutamic and aspartic acids, and demonstrating that an excess of these acids would still be available to combine with 0·4 per cent of amide nitrogen.

The total amide nitrogen of wool, as determined by Marston,[7] is 1·2 per cent. No less than 0·8 per cent is thus left unaccounted for.

Speakman and Hirst consider that Abderhalden's figures for the proportion of dicarboxylic acids is low, but such a discrepancy would require that, in terms of glutamic acid, the figure at present accepted (12·9 per cent) is inaccurate by no less than 40 per cent in terms of weight, by 8·4 grams per 100 grams of wool. As I pointed out in my previous comments, Abderhalden and Voitinovici's[8] analysis of wool is the only complete one which is available, and I am glad to see that fresh determinations of aspartic and glutamic acids are being made in the University Laboratories at Leeds. Reliable data upon the composition of wool are sadly needed. Until these results are available, it is scarcely profitable to indulge in further speculation, although, considering the relative ease of the determination of the two dicarboxylic acids, either separately or together, I am surprised at the confidence with which Speakman and Hirst prophesy that errors of such magnitude as 40 per cent will be found in the figures we already possess.

Dr. Rimington has no new point to raise. Originally, he had two difficulties, one of which has apparently been eliminated by my reply to his earlier communication. As regards the second, his difficulty has been reduced to a doubt whether re-determination of the glutamic and aspartic acid content of wool will give a sufficient increase to account precisely for the amide nitrogen as well as arginine and lysine. Even this doubt must disappear in the light of Jones and Moeller's[1] determinations of aspartic and glutamic acids in various proteins. These authors state that "new determinations of these amino acids have been made in a number of typical proteins, and *invariably higher results for aspartic acid were obtained than those previously obtained by the ester method. In several cases from 4 to 9 times as much was found.*"

Preparation of Methyl *d*-Galacturonide

A PRACTICAL method for the preparation of methyl *d*-galacturonide from the commercially available polygalacturonide derived from citrus pectin [1] has been developed in my laboratory by Mr. Sam Morell.

On heating this polygalacturonide $(C_6H_8O_6)_n$ with absolute methyl alcohol containing dry hydrogen chloride, the glycosidic linkages are partially severed and the simultaneous formation of the methyl ester of methyl *d*-galacturonide occurs. The latter crystallises as the monohydrate, $C_6H_{11}O_5COOCH_3 . H_2O$, m.p. 138-140°; $(\alpha)_D^{25} = +124 \cdot 1$ in water where *c* may vary from 1-4 per cent; no mutarotation. The methyl ester can be converted in excellent yields over the barium salt ($C_6H_{11}O_5COOBa\frac{1}{2}$) to methyl *d*-galacturonide which crystallises as the dihydrate $C_6H_{11}O_5COOH . 2H_2O$, m.p. 112-114°; $(\alpha)_D^{25} = +127 \cdot 6$ in water where *c* may vary from 2-3 per cent; no mutarotation. In a private communication, Prof. Felix Erlich, of Breslau, Germany, has informed me that the polygalacturonide used in these experiments is identical with the tetragalacturonide "-a" $C_{20}H_{28}O_{16}(COOH)_4$ that he isolated first from beet pectin and afterwards from the pectin of various fruits.[2] The details of this work will be published elsewhere.

Prolongation of Pregnancy

RECENT experiments upon rats demonstrate that pregnancy can be prolonged by 4-10 days by any of the following treatments: implantation of anterior pituitary tissue (cattle), the injection of an alkaline extract of that gland, and of extracts of human pregnancy urine prepared by precipitation with barium-alcohol and/or phosphotungstic acid. Judged by the maternal weight curve, full development of the fœtus was reached at normal term, but the birth mechanism failed. Where pregnancy was prolonged for more than 3½ days, the fœtuses were invariably still-born; in several instances parturition was protracted for 12-70 hours. Since the ovaries of such animals were found, on biopsy, to be highly luteinised, prolongation was thought to be due to the persistence of the corpora lutea formed as the result of the treatment administered. Such was the view of Teel [1] and of Levin, Katzman, and Doisy.[2] There are, however, certain indications that another factor besides the corpus luteum is concerned in maintaining the conditions of pregnancy.

(1) Expulsion of a part of the uterine contents occurred in animals the ovaries of which were highly luteinised and in which no enlarged follicles were found on histological examination. The same ovarian structure was associated, in other cases, with a continuance of pregnancy.

(2) In 2 rats in which pregnancy had already been experimentally prolonged by 2 days, laparotomy showed the ovaries to be a mass of large follicles with no corpora lutea present; in one, 8 live fœtuses were *in utero*; in the other, parturition did not take place until 46 hours later. In a third rat in which this ovarian condition was observed at term, pregnancy continued for 5 days (until the 27th day) and the maximum weight of the mother was reached on the 26th day.

(3) Pregnancy continued for 3, 4, and 5 days respectively after both ovaries had been removed on the 22nd day of pregnancy (that is, normal term) in 3 rats which had been injected with a gonadotropic extract of human pregnancy urine; and underdeveloped fœtuses were born on the 21st and 23rd days in a rat similarly injected and bilaterally ovariectomised on the 16th day of pregnancy. Two others littered 46 hours and 55 hours respectively after ovariectomy.

The evidence suggests that a factor exists which may act upon the uterus independently of the ovaries, and preliminary experiments point to its origin in the anterior pituitary. An extract rich in growth hormone, prepared after the prescription of Van Dyke [3] and held by the latter to be free of gonadotropic hormone, caused pregnancy to be prolonged 4-6½ days when administered on or after the 11th day. It is to be noted that Schockaert [4] reports an effect on testicular development in the male duck and, in our own controls, when the growth hormone from as much as 2 grams of anterior lobe tissue was injected, numerous blood points formed in the ovaries of immature *mice*, but was without macroscopic effect on the ovaries of immature rats. This amount caused a prolongation of pregnancy in rats, as described. On the basis of the rat-unit being equivalent to 4 M.U. (Laqueur and de Jongh [5]), the effect on the pregnant rat was obtained at a lower level than that at which the immature mouse ovary reacted. The 4 : 1 ratio has, however, been disputed by d'Amour, Gustavson *et al.*[6] and by Coward and Burn [7]; it is, therefore, worthy of note that even 4 M.U. (taking a 'mouse unit' as the amount which produces blood points in the ovaries of immature mice weighing 8-10 gm.) of concentrated pregnancy urine extract did not prolong pregnancy in the rat. Yet further experiments are necessary before it can be stated that the factor responsible for the failure of the birth mechanism was not that which gave rise to the typical ovarian reaction; such experiments are being carried out. Since the existence of growth hormone in human pregnancy urine has been denied (Evans and Simpson [8]), this factor appears to be precluded.

At the present stage of the experiment, the indications are in favour of the existence of some substance, possibly in the anterior pituitary, and probably identical with neither gonadotropic nor growth hormone, which exerts an inhibiting effect upon uterine motility. That such may be the *modus operandi* of the unknown substance is indicated by Reynolds,[9] who induced a state approximating to complete quiescence in the œstrin-activated uterus of castrated rabbits by a single intravenous injection of pregnancy urine extract.

Nuclear Magnetic Moments

As a possible explanation of the anomalous $g(I)$ factors of nuclear magnetic moments found in heavy and in light elements respectively by McLennan, McLay, and Crawford,[1] and by me,[2] it was suggested in both these papers that an orbital motion of some of the nuclear protons might fit the observed facts.

The recent important radioactive work proving the existence of the neutron affords, however, what may possibly be considered as an alternative or as an additional consideration. Bartlett [3] has shown that, starting with a helium nucleus, the continual successive addition of neutron, proton, neutron, proton, etc., up to O^{16}, and then neutron, neutron, proton, proton, etc., up to A^{36}, accounts exactly for all the existing isotopes; only He^5 is predicted also, but this has not yet been observed. It appears evident that α-particles, neutrons, and protons are the constituent elements of atomic nucleii. It is therefore quite possible that both neutrons and protons contribute to the production of nuclear spin. If the spin g factor of the neutron differs considerably from that of the proton, then 'anomalous' $g(I)$ factors will arise, for in one atom the nuclear spin may be largely due to protons, and in another due to neutrons.

The observations of McLennan, McLay, and Crawford may possibly be explained entirely by this alone, that is, providing the g factors are actually different; but the whole group of $g(I)$ factors, all anomalously too small, found by me in the lighter elements, is more difficult to account for. Perhaps orbital motion and variable g factor both contribute to the production of the observed anomalies.

New Infra-Red Bands Photographed in the Absorption Spectrum of Acetylene

WE have recently investigated the vibration-rotation spectrum of acetylene in the near infra-red. This absorption spectrum has been photographed in the first order of the 21 ft. Rowland concave grating which has been recently set up in a Runge-Paschen mounting. Various lengths of absorbing gas have been used, namely, 3, 6, and 9 metres, at atmospheric pressure. Employing the new Kodak zenocyanine infra-red plates, we have been able to extend our investigations beyond 1μ.

In addition to the two bands at λλ7887 and 8622 A., which have been previously reported by Mecke [1] and also by Badger,[2] two further bands have been obtained situated at λλ10164·8 and 10369·8 A. units respectively, all bands being entirely resolved and showing alternating intensity in the lines. The first three of these bands are of approximately the same intensity, and all are far weaker than the band at 10369·8 A., whilst the band which Mecke reports at 7956 A. could not be detected.

The 10369·8 A. band is interpreted as the third harmonic of the fundamental frequency ν_3 (notation after Dennison [3]). It possesses strongly developed P and R branches and a weak line near the origin (very weak Q branch ?). A few rotational lines appear to be split up into very narrow doublets, a point which is being investigated further. The general appearance of the band is closely analogous to that of the 3μ band, in which case also there is evidence of the existence of a weak line near the origin.

The other bands quoted above are interpreted as $\nu_1 + 3\nu_3$ (8622 A.), $\nu_2 + 3\nu_3$ (7887 A.), and $\nu_3 + 2\nu_2$ (10165 A.). Again P and R branches are strongly developed, but no Q branch or doubling could be seen in any of these bands.

The present interpretation of the bands agrees with the theory of Dennison [3] that only odd integral multiples of the optically active frequencies can be seen in the spectrum, and that the combinations must involve at least one of these frequencies.

Full details of the present investigation will be published later.

Nuclear Structure

UNDER the above title, Mr. James H. Bartlett, jr.,[1] has indicated a simple regularity in the known nuclei of low atomic number, without being aware of the fact that I pointed out these regularities about a year ago.[2] He states: "The purpose of this note is to point out regularities for elements of low mass, and to suggest a possible building-up principle for such elements". The discussion of the next two paragraphs has been completely covered in the paper referred to above. The diagrams were made on the basis of building nuclei from protons and electrons, but the text pointed out that the building could be made from protons and neutrons very simply. This regularity was one fact which induced Dr. F. G. Brickwedde, Dr. G. M. Murphy, and me [3] to look for an isotope of hydrogen of mass 2, as stated in our paper. Moreover, in this paper we directed attention to this simple regularity among nuclei of low mass, and reproduced the proton-electron plot on page 14. It is only necessary to interpret each diagonal unit as the addition of a neutron and each vertical unit as the addition of a proton to secure the regularity pointed out by Mr. Bartlett.

I suggested further regularities beyond A^{36}. The regularity postulates the existence of many more nuclei than are observed, and it is, of course, a question as to whether these nuclei will be observed or not. There seems to be no particular reason at the present time for withdrawing the suggestions made, however.

Oogenesis in the Indian Earthworm

RECENTLY my attention was directed to a paper by Vishwa Nath [1] on the shape of the Golgi apparatus in the eggs of the Indian earthworm, *Pheretima posthuma*. Unfortunately, Nath has apparently not seen my paper [2] on the same animal (*Pheretima posthuma*), in which I discussed the shape, origin, and structure of Golgi elements and mitochondria as observed in the oogenesis of this animal. Tests with osmic acid on fresh ovary or the usual fixed preparations failed to reveal the presence of either neutral fat or yolk; although in certain preparations swollen bodies resembling fat were found which were later on revealed as artefacts. The Golgi elements were of the usual spherical type with a definite osmiophilic thick rim and a clear transparent core inside. Prolonged osmication made the vesicle blacker. The mitochondria were granular and not filamentar. It is obvious, therefore, that Dr. Nath has completely confirmed my original findings.

Research Items

Cars of the Gods.—The ceremonial car in prehistoric times and its modern survivals are fully illustrated and studied by Dr. R. Forrer in *Préhistoire*, No. 1. In tracing its various forms and analogies, the author propounds a new theory of the origin of the wheeled cart. According to his view, it was derived from the conceptions of the character and qualities of the sun held by man at the beginning of the age of metal. The sun was then regarded as a revolving disc, which was imitated for magical purposes by a wheel or disc. This wheel was made to revolve first by being thrown in the air, then by being attached to a forked stick, which was used to wheel it about. From this developed the two, three, and four or six-wheeled vehicle, which was used for religious processionals and was afterwards put to secular uses. The theory is supported by illustrative examples drawn from rock-paintings, grave furniture, vase paintings, and other material. In the course of time, the solar car of the spring festival was associated with models or miniatures. The occupants of the sacred car take various forms, not only that of deities, but also of symbols, such as the sacred pillar, which appears in an early cuneiform inscription from Boghazkeui, or a sacred bird or animal. There are examples in which the car bears a cauldron, which served as both a fertility and a rain charm. These developments appear in the Bronze Age, and by the Iron Age had spread all over Europe and even beyond. By the Hallstadt period, the ceremonial car was gradually disappearing in Europe, no doubt owing to the spread of other religious ideas. It would appear that it was the car rather than the deity that brought benefit to mankind, and it is the important element in the rite. As, however, the idea of anthropomorphism developed, the divinity assumed first place. The importance of the car wanes, while its secular uses extend.

The Northern Paiute.—In a report on the Northern Paiute of Fort Bidwell, Surprise Valley, north-eastern California (*Univ. Cal. Pub. Amer. Arch. Eth.*, vol. 31, No. 3), Miss Isabel T. Kelly states that there is little of the old life left. The seed-gathering and hunting, which were formerly the only modes of subsistence, have fallen into disuse. A few baskets are seen and a little skin-dressing done. Little information can be obtained about political institutions, though this may be due to paucity of development; but curiously enough, religion is still more or less flourishing. Shamanistic cures are in vogue and a number of the people frequent the sweat-lodges in order to pray to the sun. It is considered especially fit that one should sweat on Sunday—an interesting secondary association, which is deeply rooted. The sweat-lodge appears to be a recent introduction from the north, although the statement that it originated about forty years ago puts it too low. Other informants declared that they had always sweated. The sweat-house was used principally by men; a few women entered occasionally. Information on shamanism was obtained with difficulty only, as the shaman believes that he will sicken and die if he divulges information. It took the form of curing and, sometimes, of weather control. The antelope shaman officiated at ceremonial hunts. A certain amount of prophecy was also within the power of the shaman. Shamanistic power was acquired through dreams, often beginning in childhood, and to many coming unsought. Anyone who disregarded the 'call' of his dreams fell violently ill. A shaman controls various kinds of animal spirits, which come to him in dreams, the eagle coming most frequently. The usual correlation of the tambourine with the shaman does not exist here.

Ancestry of the Ferret.—The domesticated ferret was generally regarded as a descendant of the European polecat (*Mustela putorius*) until G. S. Miller suggested in 1912 that certain cranial characters pointed rather to descent from the Asiatic polecat (*M. eversmanni*). The latter view is challenged by R. I. Pocock, who finds that the skulls of ferrets do not resemble those of the Asiatic polecat in the particular likeness claimed by Miller, but differ from them in the position of the post-orbital constriction (*Scottish Naturalist*, p. 97, 1932). The skulls of ferrets, however, are nevertheless distinguishable from skulls of European polecats, but Pocock suggests that the differences are due to artificial conditions of confinement and of food due to domestication. His view is strengthened by the characters of an abnormally large 'polecat-ferret' found wild in Mull, for in it the skull resembles that of the European polecat, a resemblance attributed to reversion in natural conditions to the ancestral form of an individual which was probably a descendant, immediate or remote, of an escaped pregnant female ferret.

Baits for Sheep Blowflies.—Experiments to determine the responses of blowflies to chemical substances have been made by Martin R. Freney, at the instance of a special Blowfly Committee formed to deal with the many aspects of this serious problem in New South Wales. It has been found that wool fibre, consisting largely of the protein keratin, when hydrolysed with sodium sulphide, forms an attractive medium, and this substance was tested as a bait in fly-traps. According to the figures published (*J. Council Sci. Indust. Research*, vol. 5, 1932, p. 28), the small quantity of decomposed keratin (less than 5 gm.) was not so attractive as 50 gm. of fresh sheep's brain, but the results are stated to be without quantitative significance. They show, however, a qualitative selection, for the keratin bait caught a higher proportion of female blowflies, about 98 per cent as against 84 per cent upon carrion, and it proved to be more attractive to primary blowflies, the smooth maggots of which initiate strike, than to the hairy or secondary blowflies. This is an important difference, since the larvæ of the latter are enemies of the smooth maggots; and the raising of the primary maggot death-rate from 45 per cent for brain to 83 per cent for decomposed keratin is an achievement which merits further investigation.

Freshwater Flagellates.—The attention of students of the freshwater fauna is directed to a memoir (*Mem. Mus. Roy. d'Hist. Nat. de Belgique*, No. 47; 1931), by Dr. W. Conrad, on the flagellates recorded from a series of five ponds near Louvain as the result of observations over a period of three years. The Chrysomonadina are represented by 19 genera, including 52 species (7 new), and the Volvocales by 17 genera, including 44 species. In the genus *Chromulina* the author has given particular attention to the cysts, the characters of which he regards as forming the basis of classification, and he subdivides the genus into three according as the envelope is smooth, or ornamented with ridges more or less spiral, or with spines. Keys are given for aiding in the determination of the species, and six excellent plates in colour reproduce the author's drawings from the living specimens.

Plague in Egypt.—An interesting account of the third pandemic of plague in Egypt, by Dr. A. W. Wakil, has been issued by the Egyptian University (Faculty of Medicine, *Pub.* No. 3: Cairo, 1932). The first and second pandemics of plague in Egypt occurred in the sixth and fourteenth centuries, the third commenced in 1899 and is still continuing. Although cases have occurred every year, the total number has been comparatively small, numbering rather less than 20,000 during the thirty-two years. The bubonic type amounted to 83·9 per cent, the septicæmic to 8·9 per cent, and the pneumonic to 7·2 per cent of the total. Up to the present, the city of Cairo, though well suited in many respects for the occurrence of plague, has been practically immune from plague during the present pandemic with a total of only 16 cases. The cause of this immunity is ascribed to a biological factor, namely, the presence of numerous weasels which keep down the number of rats, the principal agent in spreading bubonic plague. The main species of fleas found upon all types of rats in Egypt is *Xenopsylla cheopis*, the principal vector everywhere of bubonic plague, which numbered about eighty per cent of the total rat-flea population. Graphs are given of the relations between the incidence of plague and of the abundance of rats and rat-fleas, which show the marked relation between these factors.

Economic Botany of Cacao.—A detailed study of "The Economic Botany of Cacao" has recently been published by Prof. E. E. Cheesman (Supp. *Tropical Agriculture*, June 1932). The systematic position of the genus *Theobroma* and the status of the species *Th. cacao* L. is reviewed. Many varieties—both botanical and horticultural—are described. The most important sections deal with requirements of light and other ecological considerations, and with descriptions of the branching systems, leaves, flowers, fertilisation, and fruit production. Much discussion is devoted to the genetics of cacao growing, and to the selection and propagation of good varieties. Physiological and pathological aspects of yield and problems of quality are investigated. The paper is mainly a summary of the literature on the subject and should prove useful to all who are interested in the cacao plant.

Chromosomes and Pollen of *Kniphofia*.—The chromosomes in several species of *Kniphofia* (Liliaceæ) have been studied by Mr. A. A. Moffett (*J. Genetics*, vol. 25, No. 3), who finds the basic haploid number to be six. In *K. Nelsonii*, unlike the other species, diploid, tetraploid, and octoploid tissues were found in the same plant, both in root tips and pollen mother cells. As in certain species of *Crepis*, some roots were partially diploid and partially tetraploid. In one flowering spike most of the cells, if not all, were tetraploid or octoploid, while other spikes were diploid. In species-hybrid, *K. corallina* has a few univalent meiotic chromosomes and fewer chiasmata than the other species, while in the tetraploid pollen mother cells above mentioned two to six quadrivalents, as well as univalents and trivalents, were found. Many giant pollen grains with $2n$ or $4n$ chromosomes were also found in *K. Nelsonii*, their frequency decreasing towards the top of the spike. The majority of such grains have four haploid nuclei, and they appear to be formed directly from pollen mother cells, through a failure of the process of furrowing by which the pollen grain walls are normally formed, but this does not necessarily involve failure of the spindle mechanism.

Geology of the Lupa Goldfield.—An important contribution to the geology of Tanganyika Territory has been made by Dr. D. R. Grantham as a result of three seasons' work in the Lupa Goldfield and its neighbourhood (*Bull. 3, Geol. Surv. Dept.*, 1932, with coloured gelogical map, 1 : 100,000). A long sequence of events, including repeated cycles of igneous activity, has been established: granulites associated with banded ironstones—basic flows and intrusions—foliation and *lit-par-lit* injection of the main granitic gneiss, *G*1—shearing—some of the older dolerites—Malwelo rhyolitic and trachytic series with basic lavas now represented by chlorite-schist—Ilunga felsitic series—gneissose microcline-granite, *G*2—older dolerites—Ilunga granite, *G*4—Saza granite with peripheral diorites and 'spessartites', *G*5—younger dolerites, probably Karroo—olivine-dolerites, possibly Cretaceous—peneplanation—rift-valley movements, Tertiary alkali-lavas, and deposition of lake-beds. The 'spessartites' are regarded as a differentiation product of the Saza hornblende-granite overcharged with doleritic inclusions. They have been found to carry gold, and it is suggested that the Saza granite is the parent of at least some of the gold reefs. The lowest of the step-faults producing the Rukwa branch of the western rift valley is well exposed. The actual fault-face is almost continuously visible for a hundred miles as a nearly straight rock-wall two hundred feet or more in height, over which every river makes a waterfall to the old lake-bed below.

Apparatus for Microradiography.—M. A. Dauvillier has described recently (*J. Physique*, June) an apparatus for microradiography which is in a sense a first step to the extension of the magnifying power of a microscope through substitution of X-rays for light. It makes use of the differential penetration of soft X-rays through different elements. The X-rays, generated at about 5 kilovolts in a hot filament tube, fall on a thin section of the tissue to be studied, attached to a photographic plate. Oxygen is decidedly more opaque to these rays than carbon, whilst they are absorbed practically completely by a small quantity of sulphur, so the underlying photographic emulsion takes a record of the elementary composition of the tissue which is practically independent of the exact nature of the compounds in the latter. After exposure, the tissue is removed, the plate intensified, and the image enlarged. By using special finely grained plates, of the type devised by Lippmann for colour photography, magnifications of several hundred diameters are practicable. One is reproduced of a section of elder pith (×600) with remarkably delicate detail. The range of possible applications of this method appears very wide; the technique is not unduly involved and easily within the resources of most physical laboratories.

Raman Spectrum of Hydrogen.—An account of the scattering of light from compressed hydrogen, much fuller than any previous work of this type, has been published by S. Bhagavantam in the issue of the *Indian Journal of Physics* for May. The aim of the experiments was to extend those of Rasetti and of McLennan, and in particular to compare the observed details of the intensities and polarisation with the quantum theory of the effect due to Manneback. Judging from the spectra and microphotometer traces reproduced, the work has been performed with great care. The main body of results actually affords a quantitative verification of the Manneback theory, but there is a striking disagreement in certain details of the polarisation, which it is again suggested can only be adequately taken account of by attributing an intrinsic spin to the light quantum.

Compounds of Inert Gases.—Whilst it is probable that the inert gases of the argon group are incapable

of forming stable chemical compounds, the long-established existence of a band spectrum which can only be attributed to the molecule He_2 shows that this gas at least can enter into transitory combinations. In the first July number of the *Physical Review*, H. Kuhn and O. Oldenberg discuss the spectrum which appears round the mercury resonance line at 2537 A. when this is excited by fluorescence in the presence of a large amount of rare gas. This consists of a general broadening of the line in both directions, the broadening showing evidence of structure, and it appears that it must be attributed to the formation of a short-lived compound between the mercury and inert gas. Apparently spatial quantisation of the pair of atoms takes place on their mutual approach. The phenomenon is not confined to mercury, similar spectra being observed with thallium, and some other metallic vapours, in the inert gases. The general correctness of this explanation of the spectra is born out by the occurrence of similar structures with dense alkali vapours, due presumably to the formation of almost unstable diatomic alkali molecules in which the binding forces are in the nature of polarisations.

Treatment of Gastric and Duodenal Ulcer.—Besides the constitutional factor, these ulcers have two causes, the first being the diminished resistive power due to a circumscribed lesion of the gastric or duodenal wall, and the second the action, continually renewed, of the normal gastric juice. The methods employed for treating such ulcers are discussed by Dr. Bazzano, of the University of Milan, in a communication published in the *Rendiconti* of the Reale Istituto Lombardo di Scienze e Lettere for 1932 (vol. 65, parts 6-10). It is argued that a rational cure involves the excitation of the defensive powers of the gastric wall and the creation of surroundings favourable to cicatrixation by modifying the gastric secretion, supported by almost normal conditions of general nutrition and by repose of the patient. These considerations, in conjunction with the results of laboratory experiments showing the marked anti-peptic properties of sodium benzoate, indicated that curative effects might be expected from the administration of this salt. A number of patients were accordingly treated with daily doses of 2 c.c. of a 25 per cent solution of sodium benzoate in sterilised distilled water, applied either hypodermically or intravenously. A few injections (in either way) sufficed to produce appreciable improvement in the symptoms, and complete cures were effected after more or less prolonged treatment. Subsequent examination (after some months) of several of the twenty-four cases treated by this means failed to reveal any disturbance of the digestive apparatus.

Astronomical Topics

Total Solar Eclipse of Aug. 31.—Unfortunately, clouds obscured the eclipse for many of the observers. A telegram to the *Times* from Dr. J. Jackson at Parent reports that the clouds were less thick early in totality, and some useful coronal photographs may result from exposures with the long-focus instrument; but it is feared that the photographs with the slit-spectrographs are failures. Prof. F. J. M. Stratton at Magog has cabled to NATURE: "Cloudy, no success"; and Prof. H. Dingle at Montreal says: "No observations possible at McGill University, Montreal. Sky covered with clouds throughout eclipse."

Similar reports were received from Conway (New Hampshire) and from Derby (Vermont), also from the Mount Wilson expedition; but Dr. J. H. Moore expressed the hope that some results might be obtained from the photographs of the Lick Observatory expedition (*Times*, Sept. 1). There are better reports from Louiseville, 50 miles north of Montreal, where the sky was clear. Eight photographs of the corona were obtained with an 8-inch camera; the shadow bands were well observed, also the effect of the eclipse on the barometer, thermometer, and electrical potential. Prof. Andrew Thomson, of the Canadian Meteorological Service, who has observed several eclipses, noted that the shape of the corona was more pointed and less evenly arranged than in the eclipses of 1918 and 1919. Prof. N. Hirayama states that the expedition from Kyoto obtained a perfect picture of the corona, and colour photographs of every part of its spectrum, which show a new line (*Times*, Sept. 2).

New Minor Planet.—Another minor planet of short period has been found; it is given the designation 1932 *PB*, as the first observation reported to the Berlin Rechen Institut was made on Aug. 4 by Prof. G. Neujmin at Simeis, the magnitude being 12·7. But R.I. Circular No. 646 reports that Prof. G. van Biesbroeck had already detected it on a plate taken at Yerkes on July 30. Dr. A. Kahrstedt has deduced elliptical elements from four Yerkes observations; these indicate a daily mean motion of 1754″, and a period of 2·023 years. The only known minor planets with shorter periods are Eros (1·76 years) and the Reinmuth planet, 1932 *HA* (about 1·8 years). Hence *PB* should be followed as long as possible; Dr. Kahrstedt gives the following ephemeris for 0^h:

	R.A.	S. Decl.
Sept. 10	$20^h\ 51{\cdot}7^m$	18° 38′
18	20 58·6	18 35
26	21 7·8	18 20

The Perseid Meteors.—The August Perseids have been successfully observed this year by the regular workers in England. Mr. King has a useful series of observations extending from July 30 to Aug. 13, and similar work was done by Mr. Alcock (who recorded 479 meteors during this fortnight) and by Mr. Prentice. All three observers had clear skies through the period of maximum (Aug. 10–13): and with the assistance of other observers, notably Mr. Folkard and Mr. Lane Hall, there should be a large number of accordances, yielding heights, etc. Seven meteors were photographed on Aug. 11, one by Mr. Collinson at Orwell Park, three by Mr. Vogel at Hampstead, and three by Mr. Waters at Harrow. Various counts have been made in addition, including one from India by the vice-principal of the Nizam College, Hyderabad. It appears that the return of the stream was rather less than normal strength this year, especially in the early stages: other results remain to be worked out.

Recent Fireballs.—Several bright fireballs have been reported during the past month, an unusual number having occurred during daylight or twilight hours. The first, on Aug. 6 at 10 h. 20 m. G.M.A.T. (noon-to-noon), was widely observed from Cornwall to the Suffolk coast, and a true path will be obtainable. A twilight fireball was recorded from East Anglia in twilight on Aug. 8 at 8 h. 20 m. G.M.A.T., and a preliminary path by Mr. King indicates heights of 43 to 16 miles. Two further twilight fireballs were recorded, on Aug. 10 at 8 h. 25 m. and Aug. 14 at 8 h. 20 m.; and, by Prof. W. J. Jones, of University College, Cardiff, a daylight fireball over the north of Scotland on Aug. 20 at 7 h. 54 m. True paths of the Aug. 10 and 20 objects may be obtainable. A further fireball is reported from Cornwall on Aug. 23.

The New Botanical Building at the University of Toronto

THE University of Toronto owes much to the able and wise administration of the retiring president, Sir Robert Falconer: by the part he played in securing adequate provision for teaching and research in botany he has earned the gratitude of all who are interested in that branch of biology. One of his last acts in Commencement Week of this year was to assist at the formal opening of the new Botanical Department on June 8. After an informal luncheon given to the visiting botanists, the Chancellor of the University, Sir William Mulock; the Prime Minister of Ontario, Mr. G. S. Henry; the President, Sir Robert Falconer; his successor, the Rev. Dr. Cody, chairman of the Board of Governors, and others, walked in procession to the new building, which was opened by the Prime Minister.

Fig. 1.—Front view, showing the main entrance of the new botanical buildings of the University of Toronto.

Photo] [Peake and Whittingham, Toronto

Fig. 2.—The range of glass-houses behind a wing of the new botanical building, University of Toronto.

The Prime Minister paid a tribute to the architects, Messrs. Mathers and Haldenby, both of whom are graduates of the University, and stated that all the material used in construction was Canadian. In handing over the building to the chairman of the Governors, he said that it should be regarded as an expression of the interest of the Government, the legislature, and the people of the province in the cause of higher education.

Dr. Cody, in accepting the building, spoke of botany as one of the first subjects taught in the early days, in 1843, when the University was known as King's College. Botany was then one of several sciences for which the professor of experimental philosophy was responsible. In 1853, when King's College was promoted to university status, the Rev. William Hincks was appointed professor of natural history: one of the applicants for the chair was Thomas Henry Huxley. The present head of the department, Prof. R. B. Thomson, was appointed to that position in 1928.

Dr. Cody gave a brief account of the building, which he described as one of the most attractive in the University group. It was erected at an inclusive cost of 517,000 dollars on a site at the entrance to Queen's Park: there is a well-lighted ground-floor with three floors above arranged round a central court. The inside walls are lined with bare brick: there is about an acre of floorspace. On the ground-floor and the floor above, provision is made for plant pathology and plant physiology under Dr. D. L. Bailey and Dr. G. H. Duff; on the second floor are laboratories for morphology and the anatomy of flowering plants under the personal charge of Prof. Thomson: mycology under Prof. H. S. Jackson, seed laboratories under Dr. H. B. Sifton, and the herbarium are on the third floor. Ample provision is made for

research rooms. Adjoining the building is a range of glass-houses. Dr. Cody added that about a thousand undergraduates would be accommodated in the new laboratories.

Sir Robert Falconer invited five of the botanical delegates to give short addresses: Prof. A. C. Seward of the University of Cambridge; Prof. K. M. Wiegand of Cornell University; Dr. H. T. Güssow, the Dominion botanist; Prof. Marie-Victorin of the University of Montreal; and Prof. F. E. Lloyd of McGill University. On the following day the honorary degree of Sc.D. was conferred upon Prof. A. C. Seward.

Plant Products of the British Empire

FROM prehistoric times, man has depended to a considerable extent upon plant products, from various economic points of view. Some such products are necessities and others are luxuries. Some which were primarily luxuries have now become, with the great changes in human civilisation and habit, quite essential to human needs. These constant changes and new developments in human needs as regards the vegetable kingdom formed the basis of Sir Arthur Hill's evening discourse delivered at the York meeting of the British Association on Sept. 2, entitled "Plant Products of the Empire in Relation to Human Needs".

The economic botanist seeks to satisfy our human needs, both natural and artificial, and with the tremendous modern developments in human life and habit, his work has become of primary importance. With such a widely scattered Empire, Great Britain is able to supply itself very largely from its own colonies and dominions. Two great 'cravings' of to-day—newspapers and motor cars—are resulting in the destruction of the magnificent forests of Canada and Newfoundland and the extensive plantations of *Hevea brasiliensis*, the latex of which supplies the raw rubber, in various parts of the Empire.

Fortunately for Great Britain, it is possible, to a great extent within the Empire, to meet the growing demand for various plant products, such as oils and fats, cereals, fruit, animal foods, spices and condiments, beverages, gums and resins, drugs, tobacco, clothing, timber, etc. Certain other industries are fast disappearing, owing to changes in present-day methods and fashions. For example, indigo, camphor, and vanilla are giving place to synthetic substitutes, and cotton and flax have a strong competition in artificial silk. Another group of the Empire's plant resources, often lost sight of, because it does not appear on the world's markets, is native products used chiefly by those who cultivate them. The importance of such Empire products is scarcely ever realised until such times as famine and crop failure.

During the course of his address, Sir Arthur indicated the original homes, throughout the British Empire, of some of the economic plants. Efforts are still being made to find plants of economic value which can be grown within the Empire, with the ultimate aim of making the Empire self-supporting so far as possible. With the large increase in cultivated areas, complications such as plant diseases have been set up, necessitating the creation of an army of specialists—plant pathologists, entomologists, physiologists, etc. Rust on wheat in Canada, for example, is estimated to destroy annually £5,000,000 worth of wheat. Every year, in the British Empire alone, insects destroy enough food to supply forty-five million people.

The band of scientific workers attached to the various departments of plant economic and agricultural research throughout the Dominions and Colonies seems a rather formidable one, yet their numbers and cost of maintenance are negligible compared with the toll levied by the diseases they are attempting to overcome.

Since its inception, the Empire Marketing Board has given invaluable help in the war against plant diseases, in research on plant storage, etc., and it has spent £1,235,000 in grants for research. In many cases, too, research is supported financially by firms which depend upon the various plant products for their raw materials. For example, Messrs. Rowntree, Cadbury, and Fry are supporting the research work on cacao now being carried out at Trinidad.

The scientific problems confronting the Empire in connexion with our supplies of plant products offer a fitting outlet both for private and public munificence, and those who come forward to support the new culture of scientific research and its application to human needs will realise that they are not merely satisfying a noble enthusiasm, but are also fulfilling one of the pressing needs of the Empire.

Electricity Supply in New York

NO city in the world owes more to the advance of engineering than New York, within the boundaries of which are to be found some of the finest bridges, tunnels, subways, high buildings, and power stations ever constructed. The progress of these great undertakings is dealt with from time to time in our own technical journals, and in *Engineering* for May 13, 27, and June 17 is given a well-illustrated account of the present position of the electrical supply schemes in the city.

Fifty years have elapsed since Edison erected the first public electric supply station in Pearl Street, and that was but the beginning of the great interconnected stations by which New York and the suburbs are served to-day. The greater part of New York is now served by the Consolidated Gas Company, which in 1928 obtained control of five separate undertakings serving an area of 550 square miles and a population of 6,017,702. In 1927, the last complete year that the five companies operated as separate concerns, the total output was 4,000,000,000 kwh. and the plant installed had a total capacity of 1,400,000 kw. The capacity of the plant by September 1930 had been increased to 2,009,700 kw., and plans are now in hand for a further increase in plant designed to meet a demand which it is estimated will by 1940 be three times as great as that in 1927.

At present, power is generated in seven stations, of which Hell Gate Station has plant of 605,000 kw. and Hudson Avenue Station plant of 560,000 kw. At Pearl Street Station direct current was generated and distributed, but to-day all current is generated by alternators, the frequency being either 25 cycles or 60 cycles, frequency changers being installed so that current is available from any station for any part of the system. Interconnexion is to be carried still further by the erection of a transmission line to Schenectady, thus enabling power to be brought to New York from Niagara.

A new problem in the economical distribution of electricity arose with the erection in New York of very high buildings, and in *Engineering* for June 17

an account is given of the methods of distribution in the Chrysler Building, 1047 ft. high, and the Empire State Building, 1300 ft. high. Experience with the Irving Trust Company Building had shown that a saving could be effected by installing transformers not only in the basements but also on more than one floor of buildings more than forty stories high. In the Chrysler Buildings the high-tension feeders, therefore, are carried direct to substations with transformers on the thirtieth, sixtieth, and seventy-fourth floors, while in the Empire State Building there are substations on the forty-first and eighty-fourth floors in addition to that in the sub-basement.

The Empire State Building covers an area 420 ft. by 200 ft., and its 86 floors can house some 40,000 persons, or as many as a fair-sized town. Illumination is provided on a liberal scale, and the estimated lighting load is 6000 kw., while for the lifts, fans, pumps, and other plant electric motors of a total of 9600 horse power are installed. The substations are fire-proof brick structures and each contains four or five 600 kw., 13,800/200-volt transformers. The main vertical cables are rated for a pressure of 15 kw. and are about 3 in. in diameter with an approximate weight of 6 lb. a foot, and in the article referred to is an interesting account of the methods adopted for placing them in position and securing them.

University and Educational Intelligence

BIRMINGHAM.—Under the will of the late Mr. James Gittins Chidlaw, of Edgbaston, a member of the Court of Governors, a sum of more than £10,000 will be put at the disposal of the Council of the University for the endowment of scholarships.

MR. E. J. W. BARRINGTON of Oriel College, Oxford, has been appointed lecturer in zoology, and Dr. F. C. Champion of St. John's College, Cambridge, assistant lecturer in physics, at University College, Nottingham.

THE Council of the Institution of Naval Architects has awarded the Martel scholarship in naval architecture (1932), valued at £130 per annum for three years at the University of Liverpool, to Mr. H. G. Herbert, of Sheerness Dockyard, and the Earl of Durham prize to Mr. N. H. Young, of Devonport Dockyard.

A SURVEY of industrial education in the United States of America has been published by the Office of Education, Washington, as *Bulletin* No. 30, 1931. Among recent developments is noted the more general recognition of the importance of maintaining close contact and co-operation between the school officials and industrial firms. Committees composed of representatives of employers and employees have been especially valuable in selecting the courses to be included in the training programme, in securing properly qualified teachers and adequate equipment, and in the organisation of instruction so as best to meet the needs of industry. There is yet lacking, however, a sufficiently high degree of correlation between the courses provided in the schools of a given locality and the needs of the dominant local industries. Increasingly the public schools accept responsibility for vocational guidance with the view of placing their pupils in suitable occupations, and increasing interest is manifest in occupational information courses. Progressive specialisation in industries has led to corresponding specialisation in the schools, and the number of separate courses has been further increased by the inclusion of training for a number of semi-skilled occupations for which a short period of school instruction is now held to be worth while. Evening school work has received more attention, because money spent on training persons already employed yields a more certain and immediate return than pre-employment training. The increasing use of electricity on the farm and in the home is stimulating the development, even in small schools, of courses in simple electric wiring, the operation and maintenance of electrical appliances, and other instruction in applied electricity. Similarly, a belief that aviation will constitute a principal method of transportation in the future is leading to the provision in secondary schools of courses in model aircraft building, etc.

Calendar of Geographical Exploration

Sept. 13, 1898.—Capt. M. S. Wellby's Explorations

Capt. M. S. Wellby left Berbera on the north coast of British Somaliland, penetrated to the Omo River, and thus entered Lake Rudolf. He then turned north-west and explored part of the course of the Sobat River. In 1896, Wellby and Lieut. Malcolm had carried out a journey in Tibet, crossing the country from Leh to Kuku Nor, afterwards following the Hwang-ho and reaching Peking. This journey filled in many previously blank spaces on the map of Tibet.

Sept. 14, 1927.—The *Norvegia* Expeditions to the Antarctic

The *Norvegia*, a vessel fitted out by Consul Christensen, left Sandefjord harbour to begin that series of antarctic researches which has added so much to scientific and especially oceanographical knowledge of the region. Various scientific workers and aeronauts have taken part in the *Norvegia's* work, and, under the leadership of H. Rüser-Larsen, Queen Maud Land, Ragnhild Land, and Princess Martha Land were discovered. Early in 1931 the *Norvegia* completed the circumnavigation of the antarctic continent. The Russian explorer, Bellingshausen, in 1819-21, had previously made the circumnavigation of the continent in high latitudes, while Cook and Biscoe had made similar journeys in somewhat less high latitudes.

Sept. 15, 1587.—Davis Strait

John Davis arrived at Dartmouth after his third arctic voyage, during which he had pushed through the strait named after him into Baffin's Bay and coasted the west of Greenland to 73° N. On his first voyage, in 1585, Davis had sighted southern Greenland, which he called the Land of Desolation, had crossed Davis Strait, explored part of the Canadian archipelago, and had penetrated some distance into Cumberland Sound. On his second voyage, in 1586, he again reached the north-east coast of America. His voyages pointed the way to the true north-west passage, though it was not given him to reach it. He added much to the knowledge of the coasts of Greenland and north-east America. In 1591 he accompanied Cavendish on his voyage with the object of "searching that north-west discovery upon the back parts of America". After the rest of Cavendish's party had turned back, Davis continued the journey and discovered the Falkland Islands. He was killed by Japanese pirates when off Sumatra in 1605. Davis is also entitled to fame as an inventor; his back staff and double quadrant held the field long after Hadley's reflecting quadrant had been introduced.

Sept. 17, 1776.—Basin of the Colorado River

Father Garcés, a Franciscan missionary, reached Bac. He had set out in 1775 from the Yuma country, travelled from the mouth of the Colorado to Mojave,

and opened a new route across to San Gabriel. Thence he made a trip northward to the Tulare valley, returned to Mojave, and proceeded eastward to the Moqui country. Garcés had made many previous journeys of exploration, including a descent of the Rio Gila to the Colorado in 1771. Garcés was murdered by the Yuma Indians in a subsequent attempt to found a mission amongst them.

Sept. 17, 1822.—Weddell in the Antarctic

James Weddell in the *Jane*, accompanied by the *Beaufoy*, left on a voyage which combined whaling with discovery. Weddell had previously, in the *Jane*, visited the South Shetlands, discovered in 1819 by William Smith, and had carried out some surveys there. On this voyage he proved that the Aurora Islands, which were supposed to lie between the Falklands and South Georgia, did not exist. Weddell explored the sea which now bears his name, and reached 74° 15′ S. He brought back with him a sea leopard (*Hydrurga leptonyx*); Weddell's seal (*Leptonychotes Weddelli*) is named after its discoverer.

Societies and Academies

PARIS

Academy of Sciences, July 25 (vol. 195, pp. 293-344).—**Robert Bourgeois**: Obituary notice of Antonio Luiz de Teffé, *correspondant* for the Section of Geography and Navigation.—**Émile Guyénot** and **A. Naville**: Reduction of chromosomes in the female *Drosophila* and the theory of crossing over.—**M. Syptak**: The hypercircumferences and hyperhelixes in Euclidian spaces of p dimensions.—**Maurice Roy**: The definition and laws of the sudden variation of section in gaseous jets.—**Edmond Brun** and **Pierre Vernotte**: The measurement of the coefficient of thermal exchange between a solid wall and a current of gas.—**Henri Chaumat** and **Edouard Lefrand**: An electric motor utilising the kinetic energy of gaseous ions. A description of the construction and working of an 'ionic turbine'.—**René Audubert**: The calculation of the average radius of the granules of a dispersed system. If, at high dilutions, the electrokinetic potential be considered as obeying the Debye-Hückel theory, then the average radius of the granules of a dispersed system can be calculated by means of relations deduced from this theory.—**Radu Titeica**: The vibration spectra of some polyatomic molecules. The results of measurements of the infra-red absorption bands of formaldehyde and of acetone are given.—**Ny Tsi-Ze** and **Choong Shin-Piaw**: The absorption of light by ozone between 3050 A. and 3400 A. (the region of the Huggins bands).—**M. Bourguel**: Double conjugated linkages.—**Mlle. B. Grédy**: The application of Raman spectrography to the study of the rhodinol-citronnellol isomerism. These experiments do not confirm the formula of citronnellol suggested by Verley (α form): rhodinol contains three isomeric alcohols.—**D. Skobelzyn**: The mechanism of the phenomena of the ultra-penetrating radiation (cosmic rays).—**S. Rosenblum**: The fine structure of the magnetic spectrum of the α-rays of radium.—**H. Muraour** and **G. Aunis**: Study of the velocity of combustion, at a low temperature, of colloidal powders.—**Victor Lombard** and **Charles Eichner**: Researches on the conditions of optimum diffusion of hydrogen through palladium.—**A. Cochet** and **J. Houdin**.—The phosphates of urea and of guanylurea.—**Henri Fournier**: The results furnished by stamping tests and their relation with extension tests.—**Ch. Bedel**: The density of ferrosilicons. Thirteen alloys were prepared, ranging from 0 to 100 per cent iron. Indication of density variations were observed when the composition of the alloys corresponded to Fe_2Si and FeSi.—**Ed. Chauvenet** and **Avrard**: The determination of barium in iron ores. The iron is removed as ferric chloride by heating to 900°-930° C. in the vapour of carbon tetrachloride.—**P. Bugnon** and **A. Parrot**: The morphological value of the cotyledon in monocotyledonous umbellifers.—**Mme. Liou (Tchang-Tcheng-Houa)**: Various peculiarities of the development of the egg of *Bombyx mori* under the influence of bivoltinising agents.—**Ch. Dhéré**: The fluorescence of phyllærythrin and the structure of its fluorescence spectra.—**J.-E. Abelous** and **R. Argaud**: The formation of adrenaline in the suprarenal gland. The results of the experiments described are inconsistent with the view that the medullary substance is exclusively concerned with the production of adrenaline.—**Mme. Andrée Roche** and **Jean Roche**: The participation of the hexosephosphoric acid in the glycolysis of the blood.—**Aynaud**, **Peyron**, and **Falchetti**: Cancer of the lung in sheep and its etiological connexion with parasitic and infectious lesions.

CAPE TOWN

Royal Society of South Africa, March 16.—**W. A. Jolly**: The living organism (Presidential Address). If we are ever to attain to self-knowledge, to explain ourselves, and to determine our place in Nature and our relation to the world around, it is to advance in biology that we must trust. All that we know of the universe is due to physiological changes of some kind. In the living organism, regarded as a whole, we have a phenomenon the unity and fundamental nature of which are as essential as any of the concepts of physics. Psychology, studied by subjective methods, working in collaboration with physiology, has an important part to play in our final achievement of self-knowledge. The address concluded with an account of the methods and difficulties of modern physiological research, with special reference to electro-physiology and the time-relations of the simple reflex.—**F. Kirchheimer**: On pollen from the Upper Cretaceous dysodil of Banke, Namaqualand. These pollen forms, probably of Upper Cretaceous age, do not in the least agree with the present-day flora of the area. This serves to show, in conjunction with the character of the megascopic plant remains, that the ecological character of the area at the time of formation of the deposits was widely different from that of to-day.—**E. Reuning**: The composition of the deeper sediments of the pipe at Banke, Namaqualand, and their relation to kimberlite. The various rocks known found in the neighbourhood—granite, dolerite, and Karroo sediments—can have contributed but little to the composition of the dysodil, which is apparently the product of the infilling of the pipe by finest mud obtained from the weathering of ejected kimberlite material lying on the granite in the neighbourhood of the pipe.—**S. H. Haughton**: On some South African fossil Proboscidea. New proboscidean remains attributed to the genera *Archidiskodon* and *Pilgrimia*. There is evidence of considerable dental variability within the confines of a single living race of African elephant. The geology of the various gravels of the Vaal River area is critically examined; the possibility that the gravels of the so-called 'Middle Terrace' and the 'River-bed Gravels' may be contemporaneous is discussed.

GENEVA

Society of Physics and Natural History, May 19.—**R. Cherbuliez** and **A. Rilliet**: On methylcodeine. The methylation of the hydroxyl group of codeine is made difficult by the presence of the basic tertiary function,

the latter being more easily methylated than the hydroxyl group. This difficulty is got over by transforming the codeine into its chlorbenzylate. After methylation of the alcohol group of this quaternary derivative, the original amino group is regenerated by reduction with sodium amalgam.—**P. Rossier**: (1) The relation between the abscissæ of the extremities of a solar spectrogram (2). The author gives a better approximation, because based on more complete data, of the constants of an astrophysical formula.—(2) On the spectral type of some stars. The *K* line shows an abnormal width on some spectrograms of stars of the type A_0, obtained at the Geneva Observatory. On the majority of these negatives a spectrophotometric study based on the position of the extremities of the spectrograms appears to indicate a spectral type more advanced than A_0.—**H. Lagotala**: The geology of the mining region of Renéville, French Equatorial Africa. The author gives an interpretation of the facts observed in numerous excavations and borings. The general characteristic of the tectonics of this region is given by a series of faults, between which the compartments have had displacements in varying directions. As a result, there are sudden interruptions of the outcrops.—**J. Buffle** and **J. Corbaz**: Researches on the chlorination of α-nitronaphthalene. This operation differs substantially from the usual process of chlorination. Although without practical value, it has a theoretical interest, as it leads to a knowledge of the nature of the various intermediate compounds preceding the final products, α-chlornaphthalene and polychlornaphthalene.—**L. Reverdin**: The fauna of the middle and later neolithic of the station of Auvernier, Neuchâtel. Passing from the middle neolithic to the later neolithic, it is found that the percentage of bones belonging to domestic species increases from 49·2 to 90·4. The percentages of individuals increases from 46·7 to 72·4. For this station, the diminution in the utilisation of wild animals is very clear, but, starting with the middle neolithic only, the mean percentage of individuals belonging to domestic species was about seventy for the lower neolithic.—**P. Dive**: The risks of extrapolation in the field of geophysics. The author shows by calculation that the contradiction is only apparent, when the rigidity of the globe, such as results from the transmission of seismic movements, is opposed to the viscosity that it is necessary to attribute to the sima on which the continental masses are displaced. This contradiction arises from the fact that the experimental data of the laboratory are applied where the determining factors are magnitudes much too small compared with those factors which act in the mass of the globe. Reduced to the 'human scale' the globe appears as a body 300 times less viscous than water.—**R. Wavre**: The extension of a formula of H. Bruns. The author extends the formula which Bruns has made known for equilibrium figures to the case of a perfect fluid endowed with any movement.

MELBOURNE

Royal Society of Victoria, July 14.—**D. E. Thomas** and **R. A. Keble**: A revision of the subdivision of the Upper Ordovician and Silurian rocks of Victoria. The authors discuss the subdivisions of the two formations and propose a revision based on new and additional graptolite evidence.—**Walter J. Parr**: Notes on Australian and New Zealand Foraminifera (2). The genus *Pavonina* and its relationships. Two species of *Pavonina*, *P. flabelliformis* d'Orbigny and *P. triformis*, sp. nov., from the Tertiary of Victoria, are described and figured. *P. triformis* differs from previously known species of *Pavonina* in having the earliest chambers triserially arranged, and so resembles the genus *Reussia*. Evidence of the relationship of *P. triformis* and *P. flabelliformis* is produced by the author, who considers that the genus should consequently be placed in the family Buliminidæ, near the genera *Reussia* and *Chrysalidinella*.

ROME

Royal National Academy of the Lincei, March 6.—**L. Cambi**, **L. Szegö**, and **A. Cagnasso**: Magnetic behaviour of complex compounds. (5) Ferric dibutyldithiocarbamates. The results obtained with six isomeric compounds are analogous to those furnished by the dipropyl derivatives. Only the *NN-n*-butylisobutyl salt follows the Weiss-Curie law, the rest obeying a more complex law. This anomalous behaviour appears general in the dialkyldithiocarbamates and is shown also by ferric xanthates.—**A. Stella**: An interesting ferro-titaniferous deposit in the Arabian Desert. This mountainous deposit, known as Abu Galga, was found on ascending for about 20 km. the Madi Ranga valley, which opens out on to the Red Sea. When separated from the gangue the mineral contains about forty per cent of TiO_2.—**G. Andreoli**: Reciprocal pairs of V_2: law of the duality of linear and tangential metrics, of parallelism and metrism. (2) Formation and properties of the pair of reciprocal varieties.—**Patrick Du Val**: Observations on the surfaces of one kind which are not bases for a system of quadrics.—**M. Kourensky**: Integration of the equations to partial derivatives of the second order with two functions of two independent variables.—**L. Sona**: Orthobaric surfaces of a body.—**L. Campedelli**: Double planes with curve of branching of the tenth order.—**M. Crenna**: Deformable Ribaucour congruences (2).—**Giulio Supino**: Clebsch's problem.—**G. Krall**: The asymptotic effects of the tides on the motion of celestial bodies. (2) Problem of three bodies.—**N. Moisseiev**: The law of resistance to the motion of bodies in a pulverulent medium. (2) Special noteworthy cases.—**G. Agamennone**: Ultra-powerful horizontal pendulum with mechanical registration.—**G. B. Bonino** and **P. Cella**: The Raman spectrum of quinoline and manifestations of the carbon-nitrogen linking. Six lines have previously been observed in the Raman spectrum of quinoline, but the authors' investigation reveals nine lines. Those at 3054 (cm.$^{-1}$) and 1571 correspond with the aromatic C – H grouping and with the aromatic double linking respectively. An intense line between 1370 and 1380 must be attributed to the condensed double nucleus of the quinoline molecule; it appears very intensely in the spectrum of naphthalene, but is very weak in that of pyridine. Similar considerations apply to the lines 1142 and 764, which occur with equal intensity in the naphthalene spectrum. The line 1433, which lies within the zone (1200-1800) of the Raman spectrum assigned by Kohlrausch to double bonds, is ascribed to the double linkage between carbon and nitrogen, and is, indeed, shown by all compounds which contain a C : N group but no CH_2 group in the molecule.—**G. Natta** and **M. Baccaredda**: Mineral antimoniates of calcium (atopite, romeite, calciferous antimony ochre). Descriptions are given of various antimony ochres containing combined calcium which correspond with the formula 2 – 3CaO, $2Sb_2O_5$, 6 – $8H_2O$. They exhibit cubic lattices, unit cells of side 10·25 – 10·26 A., and lattice structures analogous to that of atopite. Romeite gives an X-ray (powder method) appearance similar to that of atopite and, like the latter, has the value 10·26 A. for the side of the unit cell and belongs to the space group O_h^7 or O_4.—**Z. Jolles**: Diazo-resins (2). As would be expected, phenylazoxycarbonamide, which is transformed into the normal diazo-hydrate by the action of alkali, gives a resin identical with that obtained directly from

diazotised aniline. Moreover, nitrosoacetanilide undergoes resinification when left in contact with alkali for some hours, yielding a product which is darker than, but of similar composition to, that derived from aniline. The passage of the nitrosoacetanilide to normal diazo-hydrate possibly takes place by way of an intermediate additive compound.—**E. Moltoni**: A selection of the birds reported by the Desio mission to the Libyan Desert.—**G. Lakhovsky**: Cosmic waves and cellular oscillations. The experiments described by Rivera (1930) indicated that the observed excitation of cellular division cannot be ascribed to cosmic waves, which have a slightly depressive influence on germination. The results of these experiments confirm the author's theories, according to which variation in cosmic waves causes oscillatory dis-equilibrium of cells and hence disease and death.

VIENNA

Academy of Sciences, May 12.—**G. Gorbach** and **H. Pick**: Ultra-violet inactivation of sucrase in its dependency on the hydrogen ion concentration and ozone. With the purest possible sucrase solutions, the influence of the prevailing hydrogen ion concentration on inactivation by ultra-violet rays is vanishingly small. This inactivation cannot be ascribed to the ozone formed, but results from direct absorption of the short-wave energy either by the sucrase itself or by substances accompanying it.—**G. Gorbach** and **D. Kimovec**: After-inactivation of irradiated sucrase solutions, and the influence of added tryptophane and yeast-gum. Sucrase solutions which have been subjected for at least ten minutes to ultra-violet radiation, afterwards become inactivated; this after-inactivation is accelerated somewhat by addition of tryptophane or yeast-gum after the irradiation. If the sucrase solution is exposed to the rays for less than ten minutes, the enzyme retains part of its activity.—**G. Gorbach** and **H. Güntner**: Yeast lipase. Lipase from brewery or pure-cultured beer-yeast exerts its optimum activity at *p*H 6·6-6·8 and at 30° C. In general, pressed yeasts are richer in lipase than beer-yeasts, and pure-cultured yeasts than brewery process yeasts. Artificial fatting of yeasts causes marked increase in their lipase contents.—**Richard Weiss** and **Ernest Knapp**: Triphenylmethanes with their benzene nuclei linked together. (7) Methylenediphenylenephenylmethane ketone.—**J. Rosenhagen**: Observations on the brightness and light-change of the planet Eros. The fact that the phase coefficient, the normal brightness, and the amplitude of the light-change of Eros are subject to wide variations is attributed not so much to physical changes as to a peculiar shape of the planet and to alternation in the position of its axis of rotation with regard to the earth. Other elements, such as precession phenomena, deformation of the body of the planet, etc., also produce secondary effects.—**Otto Porsch**: An interesting case of convergence of blossom by adaptation.—**Emil Heinricher**: Further investigations on the descendants of *Primula kewensis*.

May 27.—**Ernst Beutel** and **Arthur Kutzelnigg**: Luminescence analysis. (4) Fluorescence of zinc oxide.—**Bruno Finzi**: Results of a zoological expedition to Morocco in 1930. (5) Ants.—**Josef A. Priebsch** and **Rudolf Steinmaurer**: A year's observations of the cosmic ultra-radiation on the Sonnblick peak (3106 metres). Determinations of the ultra-radiation on this peak gave, in a slightly open iron sheath, the value 8·00 *I* (ion-pairs per second per c.c. of air at 760 mm. and 18° C.) and, in the closed sheath, 6·13 *I*, reduced to 520·5 mm., which is the mean barometric pressure on the Sonnblick. During the winter months low, and during the summer months high, values for the radiation intensity were observed, the minimum and maximum appearing to correspond respectively with the lowest and highest position of the sun. In the course followed by the variations, and in the yearly deviations (4 per cent), the results are in agreement with those obtained by Steinke in Königsberg. The intensity of the radiation is apparently not related to either the degree of cloudiness, amount of precipitation, or direction of the wind.

Forthcoming Events

Congresses

SEPT. 10–18

INTERNATIONAL CONGRESS OF THE HISTORY OF MEDICINE (Ninth Congress). To be held at Bucharest.

SEPT. 12–15

IRON AND STEEL INSTITUTE AND INSTITUTE OF METALS. Joint Autumn Meeting at the Institution of Civil Engineers, Great George Street, S.W.1; and the Institution of Mechanical Engineers, Storey's Gate, S.W.1.

Monday, Sept. 12.

Dr. H. J. Gough: "Corrosion Fatigue in Metals" (Annual Autumn Lecture), at 8 P.M.

SEPT. 12–15

PHARMACEUTICAL SOCIETY OF GREAT BRITAIN (Annual Conference). To be held at Aberdeen. Chairman's Address on Sept. 13, at 10 A.M.

Science in Social Problems

IT has continually been urged in these columns that an organised endeavour should be made to link up scientific knowledge with appropriate action in social, economic, and national affairs. Sir Alfred Ewing's presidential address to the British Association at York indicated the extent to which scientific workers are now concerned with the social consequences of their discoveries. At the present moment the disorganisation in the world's economic and distribution system, with the resultant widespread industrial depression and unemployment which has resulted from the advent of power production, is perhaps uppermost in our minds. The dangers which threaten civilisation through its failure to make a rightful use of the enormously increased productive powers with which mechanical science has endowed it, are by no means the only threat which the gap between scientific advance and moral or ethical development offers. The fourteen years which have passed since the War have, as yet, brought no check to the prostitution of scientific effort to destructive purposes. Far more destructive weapons are now available, and a repetition of the calamity of 1914 may well threaten the extinction of civilisation. As yet, however, neither scientific workers nor any other section of the community has succeeded in calling any real halt in armaments, or in inducing the Governments of the world to base their policies upon the obvious fact that the renunciation of war as an instrument of national policy is a fundamental condition of the security of civilisation.

These are major matters, but equally in lesser issues is it true that the enjoyment of the benefits of applied science involves the renunciation of deeply embedded habits and prejudices. The same forces which can minister so abundantly to our resources, our pleasures, our health, our enjoyment of life, can become a most serious public danger in the hands of careless, indifferent, or selfish individuals. The possibilities of the abuse of power increase with its magnitude in the same proportion as the possibilities of its beneficial use, but while use is dependent on knowledge, abuse is as possible in the hands of the ignorant and thoughtless as it is in those of the deliberately selfish or morally perverse.

The realisation of these conditions, coupled with the backward condition of the so-called social sciences, has already led many scientific workers and others to sound a warning note. Sir Alfred

Ewing's assertion that man was ethically unprepared for the great bounty of the engineer, that in the slow evolution of morals he was still unfit for the tremendous responsibility it entailed, and that the command of Nature had been put into his hands before he knew how to command himself, found support at the British Association meetings in the subsequent address of Prof. Miles Walker to the Engineering Section.

Prof. Miles Walker referred to the way in which vested interests blocked the way to improvement, and unintelligent control and stupid prejudice preserved the old evils, refusing to be convinced, long after science had shown the way to make things better for the people. The persistence of atmospheric pollution, mainly through domestic smoke, with the attendant loss of sunshine, and waste in dirt, health, and valuable by-products, the waste of heat and power, the paralysing influence of the middleman on the grid system —these are familiar examples of the way in which prejudice and selfishness react against the general welfare and prevent the utilisation of the benefits of applied science. Prof. Miles Walker proceeded, however, to emphasise the contribution which the engineer and man of science could make in economic and social matters, also towards the amelioration of the lot of mankind. Asserting that knowledge must form an essential qualification for executive office in the modern State, and was indeed the only sound basis for action, he suggested that in a small self-supporting State under the control of men of science it might thus be possible within a few years to demonstrate the high standard of life obtainable by modern organisation and modern methods. But as Sir Josiah Stamp remarked in a discussion in the Section of Agriculture dealing with the distribution and marketing of agricultural products, we need the moral rectitude of a Joseph, as well as his economic prudence, in planning under the conditions of to-day.

The direct outcome of the presidential address to the Engineering Section was a resolution passed by the Section expressing its conviction that the present world depression indicates that the machinery of government and finance is inadequate to deal with the vastly increased productive capacity of peoples brought about by the application of science, and the further opinion that the present economic position of Great Britain calls for far wider co-operation between the scientific community and the Government. The resolution urged the Government to invite the leading scientific institutions and societies to appoint in conference representatives to co-operate with the Government to formulate plans for dealing with the present problems facing the country.

The desire of the promoters of the resolution, however, to gain the assent of the whole of the British Association was disappointed, as when the resolution came before the Committee of Recommendations, it was turned down by a large majority. The resolution will accordingly not be passed on to the Council of the Association for adoption, although of course the Council could itself take independent action if it wished, without any suggestion from the Committee of Recommendations. It is perhaps not surprising to find that representatives of science present at the York meeting are not actively interested in the social consequences of scientific progress. Science is so specialised to-day that workers in any one branch of science are liable to have their attention so concentrated upon their own particular subjects that they see little of the field around them, and are unconcerned in its general activities or problems. The representation at the British Association meetings is still largely academic, and it may be hoped that, as the industrial element in the attendance increases, the interest in the social consequences of scientific discoveries may grow stronger.

Since the British Association has failed to take action, it is possible that the British Science Guild, which was founded in 1905 "to promote the application of scientific method and results to social problems and public affairs", may be induced to make some definite proposals for bringing scientific work and thought to bear upon social problems. At least some effort might be made to secure wider support for the task the Guild has undertaken of compiling a volume which will indicate the value of the contributions science has already made to our national progress, and the potentialities of science in the evolution of a better order of society.

Apart from Prof. MacDougall's eloquent appeal in Manchester last year for research into the social sciences, and the discussions at the centenary meeting of the British Association, there have not been wanting other similar proposals. Some time ago, Dr. G. E. G. Catlin, professor of politics in Cornell University, outlined a scheme for the formation of a social science research council in Great Britain, covering all social fields of scientific study and scientific fields of primary social relevance. The council would not only act as a clearing-house of information on scientific work in social sciences, and provide a means of obtaining competent repre-

sentatives of the social sciences on other national bodies, but would also act as a controlling organisation to which the Government could turn to sponsor independent and impartial research into social and economic problems. It was not proposed that the council should directly undertake research, or even become a mechanism for co-operative research, although the supervision of specific pieces by *ad hoc* committees might come within its scope. It was rather suggested that the council would provide a source of disinterested expert advice on social matters, which is indispensable in national planning, but is not satisfied by the Economic Advisory Councils hitherto appointed.

If it is disappointing to find that the British Association itself was unwilling to take up the suggestions made at the York meeting, it is at least encouraging that the responsibility of the man of science in these matters has been publicly admitted before such a representative gathering. It is to be hoped that the suggestions may be crystallised by some other organisation into concrete and practical proposals which can be put before the scientific community as well as the community in general. When this has been done, the disposition of the ordinary citizen at the present moment to reflect that the application of the dispassionate temper of science to the difficulties of the hour might facilitate their settlement, should encourage the scientific worker to shoulder his responsibilities of leadership, of his capacity for which discussions at the recent British Association meetings on such matters as water supply, water pollution, the planning of markets, and the prevention of disease in animals furnished copious evidence.

The Alps and the Alpids

(1) *Diskordanz und Orogenese der Gebirge am Mittelmeer.* Von Prof. Dr. Wilfried von Seidlitz. Pp. xxiv + 651 + 14 Tafeln. 72 gold marks.

(2) *Das alpine Europa und sein Rahmen: ein geologisches Gestaltungsbild.* Von L. Kober. Pp. iv + 310 + 3 Tafeln. 20 gold marks.

(Berlin: Gebrüder Borntraeger, 1931.)

THESE two works are both by geologists who have spent many years of field work studying the tectonics of the most recently folded belt of the earth's crust. They are concerned with the same subject and, whilst they are completely different in style and at first sight not much alike in conclusions, they have one feature in common. This is that the tectonics of the Alps are not the normal Alpid tectonics. The Alps are a special and unique portion of the great Tertiary fold-belt of the Alpids. West Alpine geologists, fascinated by the spectacular nappe-displacements of their own mountains, have over-emphasised, quite naturally, the importance of similar structures in the remainder of the Alpid chains. The authors of these volumes are, as it were, seeking for a new point of view from which the Western Alps will appear in their proper perspective. They show that the history of the Alpids is more than a history of young folded chains, since the reaction of tectonic islands of old folded masses, thrust-tectonics of marginal regions, fracturing, torsion movements between earth-blocks, their rising and sinking, and the associated seismic and volcanic phenomena, are all of fundamental importance in the architecture of the mountain zones. Termier's shout of 1904, "Rien n'est en place, il n'y a que des nappes", appears with respect to its second half to be a somewhat premature expression of enthusiasm.

(1) The first part of von Seidlitz's book is concerned with general matters affecting the origin of the present Mediterranean region. Morphology, palæogeography, and igneous geology are considered. The importance of median masses (*Zwischengebirge*), as a sort of tectonic islands, and their contrasts to central massifs are examined. Old tectonic kernels, relics of pre-Mediterranean orogeny, have acted as obstacles in the path of the younger folding. The divisions of the orogenic belt are developed, whilst the great importance of fractures and torsional phenomena is emphasised. The correlation of seismic and volcanic happenings with tectonic events, dealt with in detail in the first part, is stressed throughout the book, and is illustrated by many of Sieberg's seismic maps.

In the second part there are given detailed tectonic analyses of the different Mediterranean regions. This part concludes with a discussion of the many syntheses of the Mediterranean Alpids—those of Suess, Termier, Kober, Staub, Stille, and Jenny—after which von Seidlitz develops a synthesis of his own. This depends chiefly upon the recognition of main and subordinate geosynclines and of two orders of median masses.

In the third part of the book an account is provided of the whole Mediterranean orogeny. Nine tectonic zones make up the complete belt. In the centre run the folds of the main geosyncline—Sierra Nevada-Corsica-Alps-East Dinarids-Taurids; this is flanked on either side by the inner median masses, followed outwards by the folds of the subordinate geosynclines, these by the outer median masses, and finally the folds of Jura type next the

forelands, giving nine zones in all. But this picture is complicated by the torsional structures caused by northward push in the western part of the Mediterranean and a southward push in the eastern part. As a result, great fracture zones run north-west and south-east, chief of these being the Ægean, Ionian, and Balearic.

(2) Kober's style is completely different from that of von Seidlitz. It is comforting but unusual to find a scientific work in German, or for that matter in any language, in which the majority of sentences have no more than six to a dozen words. This machine-gun, Bart Kennedy style, reinforced by simple diagrams and innumerable summaries, makes Kober's exposition of his views exceedingly clear and attractive.

In his "Der Bau der Erde", Kober developed the bilateral theory of orogeny, in which fold-mountains are considered to be produced by the approach of two rigid portions of the crust, with the consequent over-thrusting of the median portion upon the two advancing blocks. On this theory, a descendant of Elie de Beaumont's 'jaws-of-a-vice' theory, the northern stem of the Alpid chain is thrust northwards on to Europe, and the southern stem southwards on to Africa. In this present work, Kober develops the theory in greater detail. He classifies each orogenic stem into the Externids (for example, the Helvetids of the Alps), the Metamorphids (for example, the Penninids), the Centralids (for example, the Austrids or East Alpine nappes), and the Internids. The last form the median masses or *Zwischengebirge* and show basin range structures. From the Alps, these zones are traced throughout the whole of the Alpid fold-mountains of the Mediterranean region. The importance of the pre-Gosau movements is constantly stressed. The last half of the book deals with general questions, such as the application of Kober's divisions of the orogenic belt to the Variscan folding of late Palæozoic date, the time-sequence of events in the Alpid folding, and comparisons and results. In this section some excellent tilts at the geophysicists will cheer all field geologists.

A comparison of Kober's present synthesis with that given in his "Der Bau der Erde" of 1928 shows little change except in the western Mediterranean. The Celtiberian chains are now outside the main Alpid arcs, the Betic cordillera being joined through the Balearics to Sardinia and Corsica. Further, a comparison of the results of Kober and von Seidlitz shows a surprisingly large amount of agreement, in spite of the great difference in treatment and outlook of the two authors. Both books are works of first-class importance to all students of tectonic geology.

The typography of these books is excellent, the misprints are exceedingly few, and the diagrams, plates, and illustrations uniformly good. Von Seidlitz's book is equipped with a fairly comprehensive index, but, as in the case of "Der Bau der Erde", Kober is satisfied with an extended list of contents—a blemish in books of this size and diversity.

H. H. R.

Creative Man

The Emergence of Man. By Gerald Heard. Pp. 303. (London and Toronto: Jonathan Cape, Ltd., 1931.) 10*s.* 6*d.* net.

THIS new book of Mr. Gerald Heard is a welcome sequel to the earlier one on the "Ascent of Humanity", which was noticed in NATURE of Aug. 9, 1930, p. 196. It is an advance upon it, because it deals more specifically with the known facts of history, and is for that reason more easily grasped by the person of average literary education and more likely to influence such a reader in the direction of co-ordinating his scattered fragments of historical knowledge. We welcome it specially because the author appreciates in a general way, and with enthusiasm and confidence, the rôle of science in building up civilisation, and leaves us in the last pages, if somewhat breathless, at least not prostrate. The richness of our discoveries and the glory of the prospect now revealed to us in the future by the action of man's mind, directed by science, cannot mean that civilisation is bankrupt and that we are standing on the brink of a moral and economic precipice. *Possunt quia posse videntur.*

The criticism which occurs is therefore not destructive but complementary; one would like the thought more completely worked out on its own lines. These lines are fundamentally sound, and often enlightening and suggestive of further thought in the same direction; but it would be a serious illusion, and sometimes a positive error, to rest in the brilliant impressions thrown out, especially in the earlier and more speculative portions. Thus it is constantly suggested that the primitive man is bursting with new ideas; life and thought are 'emerging'; a flash comes which creates an epoch; and so on. What one feels most strongly in reflecting on the—to us incomparable—slowness of the evolution in these prehistoric millennia, is the subtle and imperceptible way in which the steps must have been achieved.

Mr. Heard gives us vivid pictures of the way in

which the pre-humans drove off their first lion, made their first fire, and drew their first magic bison on the cave-wall. It is all perfectly legitimate imagination and brightens up the story charmingly, but one is quite sure that actually the process was stumbling, painful, many times repeated, and approached at a hundred different angles. It is for this reason, among others, that it pays us better to study as profoundly as possible the documents and monuments which we possess to see what they tell us of the minds of the men and the society from which they sprang. Such was the patient work of Tannery on the science of the Greeks, and the same method is now being applied to the remains of ancient Egypt, which Mr. Heard assumes unquestioningly as the nursery of civilisation.

One example drawn from this field will illustrate the difference. The pyramids, says Mr. Heard, have been treated as the work of wretched slaves toiling under the taskmaster's whip. No whip could have done the marvel; the compulsion was a spell, an urge of magic. Here we have a sound criticism and a sound suggestion of another motive at work, but it is incomplete and does not touch what, from the point of view of permanence and constructive power, is the most important aspect of pyramid building. This surely is the attainment, at that age, of accuracy in measurement and in collective working which within its limits could not be surpassed. Here are two fundamental factors in the building, not only of pyramids, but also of the whole structure of science.

A similar criticism occurs when we read Mr. Heard's account of the Romans. He finds the Roman world "hardly creative at all", which seems a strange judgment when we reflect that the Roman world, consolidating the work of the Greeks, is the one social and legal structure which has survived the ages, and that we are still living in it. It is true, of course, that they were not creative in that sense of flashes of genius which bring new things ready-made into the world. But in the other sense, of fitting things together and making men work together, they were far greater builders than the Pharaohs of the pyramids. This is an essential part of the scientific organisation of society.

One third and last point before we resign ourselves to the pleasure of reading the book again and recommending others to do the same. Mr. Heard is inclined in the latest period again to underestimate the validity of the structures of thought and of social organisation which science has built up. He sees Bolshevism as the new settlement of the world which is likely to spread, though that is only using science at its own dictation and for its own ends. Revolutionists do not really desire or respect science, as witness the treatment of Lavoisier by the Convention. But this was an exceptional incident, possible only in time of acute political passion. We cannot argue from it, or from the Bolshevists' attitude to their own men of science. The whole world, now represented outside Russia by the League of Nations, has been brought together, and is now—with some halts and spasms—functioning as a whole, through the spread of science. Why should we be always assuming that the Bolshevists are bound to be too strong for us? It is a curious fact that people who do that never mention the League of Nations, and Mr. Heard is no exception to this rule.

However, the book as a whole is fresh, suggestive, and delightful, and one may hope it will stimulate both Mr. Heard and others to similar studies.

F. S. MARVIN.

Quantitative Pharmacology

Bioassays: a Handbook of Quantitative Pharmacology. By James C. Munch. Pp. x + 958 + 6 plates. (London: Baillière, Tindall and Cox, 1931.) 45*s*. net.

THE author has reviewed in this volume all the more important papers published to the end of 1929 which deal in a quantitative manner with the effects of drugs upon the body. That the task has been laborious is shown by the fact that more than 200 pages, nearly a quarter of the book, is devoted to the bibliography. The author hopes that his work will prevent duplication of effort in the future: it is certainly worth recommending investigators to consult it before commencing a research, both for methods available and also for results already obtained, either with the drug under examination or with those of similar composition or action.

Following short sections on technique and the interpretation of results, come chapters dealing with the drugs affecting the nervous system, the circulation, respiration, and the muscles. The last two are devoted to glandular products and a miscellaneous group of special drugs, which includes antisyphilitics, antitoxins, and the vitamins.

In a work of this character, some unevenness of treatment is bound to occur: for example, the assay of the extract of the posterior lobe of the pituitary gland is described fully enough to enable an investigator to perform the test without further reference to original work. With insulin this is not the case; a number of methods are briefly referred to, but only general indications as to the

most suitable are given, and even then the details are not sufficient to enable the investigator to carry out a test without reference to the original papers.

A more fundamental criticism may be made. Sufficient distinction does not seem to be made between tests carried out without the use of a standard and those in which such a standard is employed. It might be convenient to confine the term 'bioassays' or 'biological assays' to the latter; 'quantitative pharmacology' would then have the wider significance. Owing to the different responses which different animals of the same species give to the same dose of a drug, it is not always easy to duplicate results at different times or in different laboratories, even when large numbers of animals are employed. The use of a standard of reference enables comparable results to be obtained in different tests, since it prevents unavoidable variations in technique or in animal sensitivity from affecting the final result. For this reason, emphasis might be laid on the greater accuracy of those assays which have been carried out against a standard of reference. However, the book may be thoroughly recommended to all pharmacologists and others interested in the biological examination of drugs, of both vegetable and animal origin.

Telegraphy and Television

From Telegraphy to Television: the Story of Electrical Communications. By Lieut.-Col. Chetwode Crawley. Pp. xii + 212 + 24 plates. (London and New York: Frederick Warne and Co., Ltd., 1931.) 6s. net.

THE author's declared intention of giving "a bird's-eye view of telegraphy and telephony in all their branches, showing their history, development, attainments, and future possibilities", is not quite satisfactorily fulfilled in this volume. Full weight must be given to the difficulties of presenting, in two hundred pages of simple language, a clear story of the spectacular growth of electrical communications. Yet, full weight given, the present result is a little disappointing. The need for simplicity brings with it the danger of superficiality, and the treatment tends to be somewhat patchy, especially in the later chapters.

The hobby-horse is a poor mount on which to lead a pageant of history. There are two interlinked topics running through the volume which the reviewer finds peculiarly irritating. One is the general theme expressed, for example, in this comment on Hughes's experiments: "Orthodox science had closed the door on the invention of wireless telegraphy as it has so often attempted to do in the case of other important inventions". The other is the presentation of television in a way which fails to give the reader any estimate of the true technical and æsthetic position in television to-day. The author adds to the many disservices which television in Great Britain has already suffered at the hands of its friends by devoting much of the chapter headed "Television" to a series of quotations which will make the reader ask why it should be necessary to reassert with such iteration Mr. Baird's claims to priority. The topics are, as has been said, interlinked, as, for example, by the *obiter dictum*, "Marconi, like Baird to-day, was not in the least perturbed by the opinions of the most eminent physicists or anyone else".

To suggest, as these two quotations do, that there is any valid analogy amongst the three cases of Hughes, Marconi, and Baird, is to embark on a subject which cannot be left as the author has left it. Hughes—to whom the author does less than justice—was certainly the victim of a pontifical conservatism of the most unhappy kind. Marconi—whose special contribution to electrical communications the author states very fairly—received very generous encouragement from many practitioners of "orthodox science". The encouragement was very mildly tempered by a legitimate warning about the difficulties suggested by diffraction theory, a warning which he rightly put to the test of an experiment, the success of which greatly widened the boundaries of orthodox science. Baird—to whom the author does perhaps a little more than justice—has been warned by "eminent physicists" and workers in "orthodox science" (1) that there is more than one way of approach to television and (2) that the laws of physics do not allow him to give an æsthetically satisfactory service in the particular band of medium frequencies allotted to him under the laws of man. This is a very tenuous basis for the "atmosphere of captious criticism" which the author detects around television.

The final chapter of personal reminiscences, from one who has been in exceptionally close contact with the whole life-history of wireless telegraphy, is most interesting and entertaining. The book as a whole is interesting. The remarks already made prove that it may fairly be described as stimulating; the twenty-four plates make a substantial contribution to the picture which the author sets out to draw.

Short Reviews

Organic Syntheses. Collective Volume 1. Being a revised edition of Annual Volumes 1-9. Editorial Board: Henry Gilman, Editor-in-Chief; Roger Adams, J. B. Conant, W. H. Carothers, C. S. Marvel, H. T. Clarke, C. R. Noller, F. C. Whitmore, C. F. H. Allen, Secretary to the Board. Pp. ix + 564. (New York: John Wiley and Sons, Inc.; London: Chapman and Hall, Ltd., 1932.) 37*s*. 6*d*. net.

IN this volume the editors have brought together for the convenience of their fellow-chemists the first nine volumes of "Organic Syntheses", containing authentic methods for the preparation of 260 substances. In doing this they have not contented themselves with merely rearranging the matter previously published, but have made a large number of relatively minor yet significant corrections, and have incorporated new and improved directions for the preparation of adipic acid, benzilic acid, cyclohexylcarbinol, dibenzoylmethane, *d*-glutamic acid, glycine, *dl*-methylethylacetic acid, pentaerythritol, and *n*-propylbenzene. At the same time the illustrations of apparatus have been re-drawn and the quantities of corrosive liquids and all solvents have been given both in cubic centimetres and in grams.

Not the least of the many difficulties associated with the preparation of a book of this type is the indexing; but in the volume under review these difficulties have been overcome so successfully that the indexes are among its more commendable features. There is a "Type of Reaction Index", listing most of the preparations in accordance with some general type of reaction, such as acylation, halogenation, and oxidation; a "Type of Compound Index", in which preparations are listed, where possible, according to the group introduced; a formula index, an illustration index, and a general index, all of which have been made accessible by means of thumb index marks. The references to the literature, although not intended to include every published method for a given preparation, are plentiful and up to date.

It is a work which has been carefully and skilfully compiled, and can be unreservedly recommended to every chemist who is concerned with the preparation of organic compounds.

A History of Aircraft. By F. Alexander Magoun and Eric Hodgins. (Whittlesey House Publication.) Pp. xx + 495. (New York: McGraw-Hill Book Co., Inc.; London: McGraw-Hill Publishing Co., Ltd., 1931.) 21*s*. net.

THIS is an extremely readable American publication, which does not, as several others have recently, give undue prominence to American achievement. Its record ranges from Archytas in 400 B.C. to Post and Gatty in 1931, and concludes with a chapter entitled "The Present", which happens to be principally an attempt to look into the future.

The authors claim to have exercised Lytton Strachey's requisite for the historian, "ignorance, which simplifies and clarifies, which selects and omits . . .", and in the historical sections, using a restraint compatible with this humility, they have produced a remarkably concise and accurate précis of the world's aeronautical history, both mythological and actual. With contemporary history they are less happy, in that they have been led into reporting opinions, obviously biased by local outlooks, that they, as historians, should have avoided. For example, it will be news on the eastern side of the Atlantic that Sikorsky, in Russia in 1916, was the first person to produce a successful twin-motor aeroplane. Perhaps the literal accuracy of this statement turns upon one's interpretation of the word "successful". Also, that Hawker after his attempt upon the Atlantic flight in 1919 "vanished from the public stage", apparently because of his political indiscretions. The last chapter, with its attempts at forecasting the technical developments of the future, is a tactical error, and mars what otherwise is an interesting and logically written book. It is not in place in a history, neither do the authors appear to be technically able to deal with it.

The general lay-out is excellent, divisions being made according to classes of aircraft. This, combined with a chronology at the end of the book, makes reference particularly easy.

Gems and Gem Materials. By Prof. Edward Henry Kraus and Dr. Edward Fuller Holden. Second edition. Pp. ix + 260. (New York: McGraw-Hill Book Co., Inc.; London: McGraw-Hill Publishing Co., Ltd., 1931.) 18*s*. net.

THE second edition of this useful work contains much new material, and is even more fully illustrated than the first. The work is divided, as before, into three parts—the first dealing briefly with the general properties of minerals, the second being concerned with descriptions of the individual gem species, and the third part containing tables of physical properties, etc., conveniently arranged for reference. A good index is provided.

The additional information concerning synthetic corundum and spinel embodied in the chapter on manufactured stones makes this one of the most valuable features of the book. A further improvement is to be found in the section on amber, which now provides an excellent account of the natural material and the properties by which it may be distinguished from its various imitations. The chapter on the cutting and polishing of gems has also been expanded. Less than two pages are allotted to the description of pearl, and the treatment is inadequate for so important a gem. The cultured pearl is briefly mentioned, but no account is given of the important modern methods used for distinguishing between natural and cultured pearls.

A mass of information is conveniently summarised in the concluding table (Table XI.). In this, wrong values are given for the specific gravity of benitoite, and the refractive indices of azurite and zircon—misprints which should be corrected in a future edition. The book is well produced and pleasant to handle, covering a wide field in a surprisingly small space. B. W. A.

The Microscopic Examination of Cattle Foods. By S. T. Parkinson and W. L. Fielding. Pp. viii + 97 (15 plates). (Ashford and London: Headley Bros., 1930.) 6*s.* 6*d.* net.

THE growing demand for detailed knowledge of the constituents of cattle foods has brought into prominence the need for adequate methods of analysis. Microscopic examination affords the only certain means of identification of the materials present, and hitherto a concise and systematic treatise dealing with the subject has been lacking. Parkinson and Fielding have now elaborated their own methods and have successfully attempted to set them out in such a way as to provide the student with a ready means of attacking a problem which bristles with difficulties.

The preliminary chapter is devoted to a description of methods, which are given in detail and would appear sufficient to meet most situations that are likely to arise. The main food plants are then dealt with in groups, including oil-containing plants, cereals, and leguminous plants, with a further chapter on such miscellaneous constituents as weed seeds, beet pulp, potato residues, and spent hops. Methods of identifying undesirable adulterants, such as sawdust, are also given to provide a test for purity. For each group, tables have been drawn up which enable comparisons between the different constituents to be made readily by selection and elimination. Additional information is provided by annotated photomicrographs of the chief features described and of the principal weed seeds. The volume meets a distinct need, and should prove most useful on the commercial side, as well as for training agricultural students in a better understanding of certain aspects of animal nutrition.

Cacao. By Dr. C. J. J. Van Hall. Second edition. Pp. xviii + 514. (London: Macmillan and Co., Ltd., 1932.) 28*s.* net.

DURING the last few years, increasing interest has been taken in problems relating to cacao cultivation and production. It is singularly appropriate, therefore, that a second and revised edition of what is generally regarded as the standard work on the subject should now make its appearance. In this new edition, the author, an acknowledged authority with wide experience of the crop, includes the results of all the outstanding work on cacao that has been carried out in various parts of the tropics since the appearance of the first edition in 1914.

The most notable addition to the work is the chapter devoted to breeding and selection. Here the author outlines the methods that are being adopted in such countries as Java, Trinidad, and Surinam to improve the yield and quality of the crop, and does not omit to point out the numerous difficulties that have to be faced. The information relating to pollination and fertilisation is of special botanical interest, as these phenomena in cacao have been so long shrouded in mystery, and it is only in recent years that light has been thrown upon them. The account of the improved technique in budding that has now been evolved should be of value to all those concerned in any way with propagation. In the chapter devoted to pests and diseases much that is new has been added, including accounts of the valuable work that has been carried out in this sphere in the West African cacao-producing countries.

The Phenomenology of Mind. By G. W. F. Hegel. Translation, with an Introduction and Notes by J. B. Baillie. (Library of Philosophy.) Second edition, revised and corrected throughout. Pp. 814. (London: George Allen and Unwin, Ltd.; New York: The Macmillan Co., 1931.) 25*s.* net.

THE philosophy of Hegel is for the very large majority of people a closed book. Of all the philosophers, he is by far the most difficult to understand, and Sir James Baillie has performed a very great service in translating and editing a new edition of his "Phenomenology of Mind", which may be fairly looked upon as Hegel's *magnum opus*. The subject matter is, however, so abstruse that it is very difficult to understand, and a modern psychiatrist might be forgiven for regarding some of it as definitely dereistic thinking, a term which Bleuler has well defined as thinking away from reality.

The translator has very much lightened the reader's task by a well thought out and reasoned introduction of some fifty pages. We think it might well have been indicated, when discussing phrenology and physiognomy, that the ideas of Lombroso are not necessarily accepted by scientific criminologists of to-day. The value of the table of contents has been very much enhanced by the addition in brackets of remarks of the translator. These help to clarify the plan of the work, and help the reader on what cannot really be otherwise than a weary way.

Solutions superficielles, fluides à deux dimensions et stratifications monomoléculaires. Par André Marcelin. (Recueil des Conférences-Rapports de Documentation sur la Physique.) Pp. 163 + 4 planches. (Paris: Les Presses universitaires de France, 1932.) 80 francs.

M. MARCELIN's book will be heartily welcomed by all those workers who are concerned with the chemistry and physics of surface phenomena. The author opens the book with a historical exposition, and, after a brief discussion of the physical state of surface solution, goes on to describe in full detail and very clearly the experimental methods in use to-day. He then, by means of a very full discussion of surface solutions of oleic and other acids, illustrates the properties of and regularities shown by such solutions.

Very interesting chapters follow, dealing with pseudo-solutions and their transformation into true surface solutions, and with the equilibrium between a solution and a surface solution. The influence on the Volta effect produced by the presence of a monomolecular layer is very carefully examined, and the book closes with an account of the properties of thin films. It is fully documented, is written with admirable clearness, and is a notable addition to a notable series. ALLAN FERGUSON.

Some Aspects of Applied Geophysics *

By Prof. A. O. RANKINE, O.B.E.

PERHAPS some apology, or at least explanation, is necessary for the choice of a subject for which I have not even been able to find a satisfactory title. Applied geophysics may clearly be taken to include certain aspects of meteorology or oceanography, or, indeed, any branch of knowledge in which physics is applied, in the service of mankind, to the elucidation of the properties of the earth. I propose to deal with what is in fact only a limited field of work. Put briefly, it covers the application of physical methods to the examination, without digging or boring, of what lies beneath the surface of the earth at relatively shallow depths of less than a few thousand feet. The application is more particularly directed to the discovery of deposits of economic importance, such as minerals or oil, or the structural formations with which they are likely to be associated.

Truly this is a subject as different as it could very well be from those flights of theoretical physics—relativity, quantum theory, wave mechanics, and the like—which those of us with slower minds and more pressing other occupations try so desperately to follow. In our admiration and, perhaps, envy of the apparent ease with which the pioneers in these new fields make progress, we are inclined, wrongly, I think, to allow it to be assumed that modern physics and atomic physics are one and the same thing. It should not be overlooked that physics is making rapid strides forward also in other directions. Much that is new in the precision of measurement, in the choice of methods, and in the invention and design of physical tools for the attack on old problems hitherto unsolved, has been added to our knowledge in recent years. This is true with regard to the particular branch of physics we are now to consider. Its fundamental basis is not new. It involves no appeal to, let us say, wave mechanics; the old gravitational theory of Newton and the electromagnetic theory of Maxwell serve well enough our purposes. Yet its successful application continues to demand the highest experimental skill that training in physics can provide, and initiative ability equal to that more frequently directed in less practical channels.

The subject is also a border-line one, and, perhaps for that reason, has not received so much attention as it deserves, at any rate in Great Britain. Its practice involves the co-operation of geologists with physicists, except in those rare examples of the same person being expert in both branches of knowledge. It was a famous geologist, the late Prof. de Böckh, who suggested to the equally famous physicist, Baron von Eötvös (whose work we shall consider more fully later), that the Eötvös torsion balance should be used to locate and delineate buried salt domes—geological features with which oil is frequently associated. Prof. de Böckh once told me that at first Eötvös was horrified at the idea. He regarded the use of his instrument for such an economic purpose as debasing science, and it was only with great difficulty that he was eventually persuaded to initiate what has now become a common and successful practice in various parts of the world.

I may perhaps mention, too, that when I first became interested, about five years ago, in applied geophysics, I was very doubtful of its use. Could conditions underground, I asked myself, ever be so simple and free from complications that physical observations on the surface would point unequivocally to the solution ? The answer to this question is, generally speaking, in the negative ; but here the geologist comes in again. He carries out his preliminary survey by his own methods, and is often able to indicate both the limited region where a geophysical survey seems desirable and, in a general way, the kind of formation which is to be sought, thus enabling a suitable choice of method to be made. He provides, in fact, the *selection rules* for the geophysicist, in much the same way as the quantum theorist does for the spectroscopist, as regards both where to look and what to expect to find. It is true that sometimes a *forbidden* result persists in obtruding itself inconveniently upon the geological interpretation, just as a *forbidden* spectral line may refuse to be extinguished. But usually the solution of a problem has to depend upon the combined result of geological and physical evidence, and is only approximate at that.

It is mainly the physical basis of the work that I wish to review. Here I should point out that this limitation will exclude 'divining', whether for water or any other underground feature. Innumerable claims of successful use have been made for the divining rod and similar indicators, but the *modus operandi* has never been explained, and none has been established on an acceptable physical basis. But I am glad to escape from this highly controversial ground by defining in a sufficiently exclusive manner what is a geophysical method in relation to the search for minerals. The basis of every geophysical method is the differentiation, usually abrupt, of some physical property as between rocks. The four principal methods—gravitational, magnetic, seismic, and electrical—depend, in fact, upon differences, in the various media underlying the earth's surface, of density, of magnetic susceptibility, of velocity of elastic wave propagation, and of electrical conductivity respectively. Associated with these variations of physical properties, either naturally or through stimulation by artificial means, there are produced, at or near the earth's surface, calculable physical effects which may be capable of measurement by suitable apparatus. There must be something physical to measure, and the instrument must be able to measure it.

* From the presidential address to Section A (Mathematical and Physical Sciences) of the British Association, delivered at York on Sept. 2.

THE GRAVITATIONAL METHOD

I do not think that Eötvös has yet received in Great Britain the full recognition which his work deserves. Possibly this is because the early accounts appeared in rather inaccessible journals; or, possibly, there were real doubts concerning the validity of his claims. I remember, as a student, hearing vaguely about his experiments—and his name, without anyone knowing how to pronounce it. In the same lectures we learnt much fuller details of Boys's classic measurement of the constant of gravitation, without realising how remarkably similar in essential form the Eötvös and Boys instruments were. But the fact is that when Boys was inventing and making the quartz fibres for his torsion balance to weigh the earth, Eötvös had already tackled successfully the difficult task of making robust and portable for field work another torsion balance of not greatly inferior sensitivity. While Boys was busy with his measurements in a constant temperature cellar, Eötvös was completing the protection of his portable instrument against the temperature variations inevitable in the rigours of the field. A few years later he made notably successful gravitational surveys on the frozen surface of Lake Balaton and on the Great Hungarian Plain; but it was not until Shaw and Lancaster-Jones had demonstrated in 1923 that an Eötvös balance, acquired for the Science Museum before the War, behaved according to specification, that the remarkable nature of Eötvös' achievement began to be appreciated here.

Even now I do not think it is well enough understood how small were the effects which Eötvös measured under the unfavourable conditions of field work. We can illustrate this in a very striking way. The earth's gravitation field, even apart from local irregularities, is not uniform, or, rather, spherically symmetrical. Owing mainly to the earth's rotation, the apparent value of the gravitational intensity increases in passing from equator to pole. The total change is about 5 cm./sec.^{2}, and the maximum rate of horizontal variation is at latitude 45°. In this region the change of g for a step of one metre northwards is 8×10^{-7} cm./sec.^{2}, or, approximately, only one thousand millionth of the gravitational acceleration. This the Eötvös torsion balance was capable of indicating definitely, being several times as large as the limit to which the instrument would respond. Further, the measurement could be made with the instrument occupying a single position in a space of less than a square metre, simply by making observations with the apparatus as a whole in a number of different azimuths. Eötvös, in effect, multiplied by a thousand the accuracy of measurement of terrestrial gravity variations.

This remarkable sensitivity was secured by deliberately excluding gravity itself from exercising any control in the instrument, which was constructed so as to respond only to *variations* of the gravitational field.

It would take too long to describe the instrument, and at the same time do justice to those used in other branches of geophysical surveying. It must suffice here to indicate that the Eötvös torsion balance provides means of measuring, normally by observations of the changes of torsion accompanying changes of azimuth of the instrument as a whole, two properties of the local gravitational field, each having magnitude and direction. The magnitude of the first, for which a satisfactory name has not yet been devised—the *horizontale Richtkraft* according to Eötvös—is the product $g(c_1 - c_2)$, where c_1 and c_2 are the greatest and least curvatures of the local 'level' or equipotential gravitational surface; its direction is horizontal and in the vertical plane of least downward curvature. The other departure from gravitational uniformity which the balance measures is the *gravity gradient*, or the rate of change of the vertical gravitational intensity with horizontal distance in the direction in which the change is greatest. It is a vector, and both its magnitude and direction can be obtained from the instrumental observations.

The reaction of the instrument to these two differential 'fields' provides the means of measuring the particular gravitational distortions which they represent. This part of the work is pure physical measurement of a straightforward character, and attaining, as I have indicated, a surprising degree of precision. It is in the interpretation of the results that the real difficulties arise. The problem is to ascertain to what extent the gravitational irregularities measured are due to density differences in the buried structure, and to assign to the latter a position and shape consistent with the observations. In country where the surface is otherwise than virtually horizontal it is necessary to survey its irregularities and make calculated allowances for their contribution to the total measured gravitational distortion. This topographical effect may indeed sometimes be so large in comparison with that of hidden structure as to render gravitational surveying ineffective. The earth's rotational effect, of course, has always to be eliminated, but this presents no difficulty. What remains after these corrections constitutes the data for geophysical interpretation; and this is the stage where the geologist's 'selection rules' have to be applied. As in all geophysical methods, interpretation is necessarily indirect. Underground structures, agreeable to the geologist's experience, have to be taken as hypotheses, and tested by calculation and comparison with the data provided by surface observations.

I have, rather regretfully, to leave at this stage this part of my subject. My recent practical experience with torsion balances has aroused in me the greatest admiration for the work of the original inventor and his successors, and for the skill and precision with which most of these remarkable instruments have been constructed by the makers. It comes as something of a shock, even though we do not doubt the universal law of gravitation, to see for the first time a small mass of gold being attracted by a neighbouring lead sphere a few inches in diameter. With a torsion balance at our disposal the same becomes commonplace, and is indicative of the great power of these instruments

for geophysical purposes. Accumulated evidence from the field confirms this view. There is convincing proof that extensive underground features, such as salt domes, limestone anticlines and synclines, rock faults, and deposits of hæmatite or of brown coal, produce, if not too deeply buried or masked by complicating irregularities, gravitational disturbances large enough to lead to their delineation.

THE SEISMIC METHOD

The seismic method of prospecting began to be used about 1919, chiefly owing to the initiative of Mintrop. To some degree it has replaced the gravitational method, on account of the greater speed with which it enables a given area to be surveyed—a most important economic criterion, of course. But there are other important reasons why, under certain conditions, it must be preferred. If, for example, the topography of the country is too irregular for the corresponding corrections to be applied reliably to torsion balance observations, gravity surveying is excluded; and seismic work, which is not so sensitive to surface conditions, may still prove of value. Again, the structure to be determined may itself settle the choice of method. For example, if the problem were to determine the depth of a horizontal interface of discontinuity between two strata of very great extent, the torsion balance would not find anything to measure; the seismic method, on the contrary, would be confronted, as we shall see, with its most direct and simplest task. But while admitting these undoubted advantages, and recognising the many notable successes of seismic surveying under suitable conditions, it is necessary to state that this method does not yet rest on so sure a theoretical foundation as the law of gravitation: nor do the portable seismographs employed give records so unambiguous as the readings of the torsion balance.

The basis of the seismic method is the same as that underlying the investigations of the propagation of earthquake shocks in relation to the determination of the structure of the earth's crust. The difference is only one of degree. In so far as there is a theory of natural earthquake propagation, it serves also for the seismic method of geophysical prospecting. In trying to determine the depth of an underground stratum, the most direct method of attack would be to measure, if possible, the time of travel of a particular disturbance from the surface to the interface and back to the surface after reflection. This method has been used with great success in determining the depth of the ocean by means of the Admiralty echo-sounding machine. But it fails in application to the solid earth, for the reason that the attenuation of vibrations with distance is far greater in the earth than in the sea; consequently, much larger initial disturbances have to be used—in fact, violent explosions. Even if—as ought always to be done for the sake of efficiency—the explosion is arranged so that the surface of the ground is not broken, thus eliminating danger to observers, the delicate seismographs cannot as yet be properly protected against the direct effect. They would thus be so greatly disturbed as to mask completely the onset of the small reflected disturbance arriving shortly after. This effect, indeed, persists to a less but still important degree even when the seismograph is removed to quite large distances from the explosion. It is true that some important results have been obtained by employing this so-called reflection method, but the reading of the records is a matter of considerable uncertainty, owing to the difficulty of identifying the time of onset of the reflected disturbance in the midst of the effect of that propagated directly.

This uncertainty has led to the more general adoption of a method, properly called the diffraction method, although the term 'refraction' is sometimes incorrectly used. Its great advantage is that it enables the inevitably feeble disturbances, which have penetrated to and through the lower medium, to reach the seismograph, under certain conditions, *in advance* of the much greater direct wave. Consequently, the times of arrival of these indirect, or diffracted, disturbances are recorded unmistakably upon the seismogram, however much the instrument may be agitated later on.*

The principles of the method can be readily applied to structures less simple than a single horizontal interface; and the observations obtained in the field, plotted on time-distance graphs, enable such features as the slopes and curvatures of strata and the depths of more than one successive bed to be recognised under favourable conditions. For success the principal requirement is a large velocity-ratio as between the rocks constituting the various beds. Salt domes under alluvial deposits, for example, are in this respect suitable structures, and the location of many such domes was the first achievement of the seismic method. It has also been employed with valuable results in determining the underground contours of limestone anticlines and deep-seated granitic basements at depths of several thousand feet.

THE MAGNETIC METHOD

We pass now to the magnetic method. In actual practice it is the simplest and least costly. It consists of measuring, with suitable portable magnetometers, local variations of components of the earth's magnetic field, usually the vertical and horizontal intensities. The instruments which have been designed for the purpose enable observations to be made quickly, so that a large number of stations can be occupied and a wide area covered in the course of a single day. Under suitable conditions, therefore, much information regarding underground structure may be obtained by means of a survey lasting only a relatively short time and involving comparatively little expense. But it should be pointed out that this apparent economy has sometimes led to the method being employed on problems for which it is at present unsuitable, and to claims being made as to its performance which are doubtful.

It is necessary to bear in mind that the basis of magnetic surveying is the differentiation of rocks in

* The theory and practice of the seismic method is discussed in articles in NATURE, 123, 684, 718, May 4 and 11, 1929.

respect of magnetic susceptibility, and the consequent discontinuities of magnetisation under the influence of the earth's general magnetic field. For the field distortion thereby produced at the earth's surface to be marked, it is necessary for the responsible rock structure to have a large susceptibility; this implies that only highly ferruginous rocks will be easy to find.

I do not mean to imply that the magnetic method of surveying is limited to the detection of ore bodies like magnetite. Igneous rocks generally, and particularly basalt, may contain considerable quantities of iron, and consequently possess an effective magnetic susceptibility much larger than non-ferrous materials. There is abundant evidence that structures of such rocks have been determined, under favourable conditions, by the use of magnetic variometers. But if we are to hope to bring within the scope of the magnetic method non-ferruginous underground formations, we must improve greatly the sensitivity of the instruments, and at the same time exclude the operation of certain disturbing factors.

The chief difficulty with the variometers at present available is the application of the corrections for diurnal variation of the earth's field and for temperature changes. If we could escape the necessity of applying the corrections which these important effects involve, we should feel much safer in attaching significance to anomalies only a few times larger than the limit of measurement of the apparatus.

A year ago I thought I saw the way to do this, and brought a method before this Section of the British Association. It was to make use of the essential principle which gives to the Eötvös gravity balance its extraordinary sensitivity, namely, to measure the space-variation only of the forces in question. I found later that Eötvös himself had worked on these lines, and actually constructed an instrument partially fulfilling the conditions; although it is not clear that he realised the full significance of complete success. I have to confess that unexpected practical difficulties of construction have so far prevented realisation, but I have not given up hope that a magnetic instrument can be constructed to operate in the same way as the proved gravity instrument. Accordingly, it may be worth while to indicate what a device of this kind might be expected to achieve.

The chief virtue of such a magnetic torsion balance is that it would discriminate between *time-variation* and *space-variation* of the earth's magnetic field. The variation with time of a magnetic field remaining spatially uniform would not affect it; it would respond only to a sufficient distortion in space. Calculation shows that with the magnets and suspending wires now available we could anticipate an instrument which would be just about sensitive enough to respond, in the average magnetic latitude, to the non-uniformity of the earth's main field. The additional lack of uniformity arising from diurnal variations, or even magnetic storms, is by comparison small, because the amplitude of the variations is only a small fraction of the total field, and they are very widespread in character; consequently, they would fail to disturb the instrument appreciably. We should therefore be able to attribute the distortion observed solely to local magnetic features, apart from a nearly negligible correction for general earth's magnetism. The effect of changes of temperature also would be comparatively small, for they would be proportional to the variation of field intensity over the limited space occupied by the suspended system, instead of to the full intensity at the station. In the gravity torsion balance they are, in fact, negligible, and they could be made equally so here.

Electrical Methods

I have left until last reference to electrical methods, not because they are of less importance, but because I am less familiar with them, and could not speak with any of the authority which comes from practical experience. Accordingly, I shall simply use this opportunity of directing special attention to the work of the Imperial Geophysical Experimental Survey ("The Principles and Practice of Geophysical Prospecting": Cambridge University Press, 1931), which operated in Australia from 1928 until 1930. This survey, under the leadership of Mr. Broughton Edge, whose extensive experience of electrical surveying is well known, was concerned chiefly with electrical investigations. It is, I think, no exaggeration to say that the report is the most comprehensive and authoritative treatment available of the subject of electrical surveying.

Future of Geophysical Surveying

Much, however, remains to be done in all branches of geophysical surveying, in order to put it on a more secure basis and to determine more certainly the scope of its applications. It must be confessed that until quite recently practically all the work was being done by German investigators. By its nature the work is necessarily costly. Except as regards some aspects of the construction and improvement of instruments, it cannot be confined to a laboratory; and, with the same limitation, it can rarely be an individual effort. Effective research in the field implies adequate scientific personnel, transport, labour, and materials, in addition to the instrumental equipment. If we are to make substantial progress in this direction, the expense must be faced.

I recognise that it would be foolish, as well as useless, to press now for the initiation of any costly schemes. But it is permissible to hope and believe that the subject will not be completely neglected in these difficult times. We can occupy the lean years in making ourselves more familiar with what is already known, and in conducting new investigations on a modest scale—as, indeed, is being done at South Kensington by the Imperial College with the assistance of the Department of Scientific and Industrial Research. Then, when the fat years come, and the mining industries again call for the help of geophysicists, we shall be found, at least, not wholly unprepared.

The Adequacy of Human Dietaries

HOW far the food ordinarily consumed by different individuals provides an adequate amount of the different dietary essentials, and to what extent an improvement in the diet might lead to a general improvement in health and wellbeing and a decrease in the incidence of disease, are important questions. The answers depend in the first place upon a knowledge of all the factors which go to make up a complete diet and of the quantity and quality of the food actually consumed. The essentials of a diet are now well established, but our knowledge of the adequacy of common diets is still very incomplete. The investigations of Cathcart and Murray on the diets of a number of families in St. Andrews have already been described (NATURE, **127**, 897, June 13, 1931): the same authors have now published the results of an investigation into the diets of 56 families in Cardiff and 57 families in Reading.*

In this survey a horizontal instead of a vertical section of the community was selected for investigation, since for all practical purposes further examination of the diets of those comparatively well off appeared to be unnecessary. The numbers involved in the study were 378 at Reading and 370 at Cardiff.

It was found that the 'man' value per family was 4·55 at Cardiff and 4·35 at Reading, the 'diet man' values being respectively 4·54 and 4·30. The calorie consumption per 'man' per day was at Cardiff 3174, obtained from 79 gm. protein, 114 gm. fat, and 441 gm. carbohydrate: the corresponding figures for the Reading families were 2906 cal., 75 gm. protein, 101 gm. fat, and 408 gm. carbohydrate. The distribution of the calories between the proximate principles was, in each case, about 10 per cent from protein, 32-33 per cent from fat, and 57 per cent from carbohydrate, a very similar distribution to that found at St. Andrews. The Cardiff families spent more money on both food and rent than the Reading families. Comparison with other studies indicates that these values are more nearly comparable with those of the Glasgow artisan class than with other groups in Glasgow or Dundee. The fat consumption of the English working classes appears to be much greater than that of the Scottish. The amount of the income spent on food is 70-90 per cent in Glasgow, 45 per cent in Dundee, and 57 per cent in Cardiff and Reading.

At Cardiff the families with the largest incomes consumed most protein: at Reading this was not the case. The Cardiff families also derived a slightly greater proportion of their protein from animal sources. In the case of the unemployed families, the Reading diets were found to be of lower caloric value than the Cardiff, but contained a higher proportion of fat. 8 Cardiff and 12 Reading families consumed 2500 cal. a man or less. This was found to be due chiefly to the improvidence of one or both parents: at the same time it was noted that the English families spend much more of their weekly income on rent than the Scottish.

At least 73 per cent of the mothers in the Cardiff families could be classed as good, and 93 per cent in the Reading families. It is of interest to note that in Cardiff the 'bad' mothers spent most on food (70 per cent of the total income), whilst in Reading it was the 'good' mothers who utilised the greatest proportion of the family income on the purchase of food (58 per cent).

Little or no evidence of any real under-nutrition, as compared with the rest of the community, in the children of the relatively poor families was obtained.

In this study, only the quantitative aspects of the diets were considered, and no attempt was made to determine their adequacy in minerals or vitamins. The Advisory Committee on Nutrition to the Ministry of Health has recently examined and criticised diets in common use taking these aspects into consideration.† A simple method of calculating the calorie, protein, fat, and carbohydrate content is described. It is pointed out that at least 80 gm. protein and 50 gm. fat should be consumed daily and that the percentage of calories derived from carbohydrate should not be much greater than 66. About 37 gm. protein or 5 per cent of the total calories should be animal protein, of high biological value: this can be obtained from cheese, eggs, fish, milk, and meat. Minerals and vitamins are provided by milk and milk products, fresh salad vegetables and fruits, liver, fish, especially fat fish and fish roes, and eggs: their intake should be adequate if each individual consumes 1 pint of milk daily, partakes freely of cheese, if one orange or tomato or helping of raw salad is taken daily, if 1 oz. a day of butter (or vitamin margarine) is given and if a fat fish such as herring appears in the winter menu once a week (or half a teaspoonful of cod liver oil is taken once a day).

A diet is not usually deficient in calories, but may be so in first class (animal) protein and in the protective foods which supply the minerals and vitamins: it is then a simple matter to improve it by supplying these dietary essentials. Scrutiny of the diets in the children's homes visited showed that cheese was rarely given, that salads were not supplied in winter, and that ordinary (and not vitamin) margarine was generally used. It is recommended that the diets be improved by giving 1 pint of milk a head each day, by including green vegetables and carrots in the dietary, as well as apples or oranges, by using vitamin margarine, and supplying cheese, ox liver, fish roes, herrings, tomatoes, and watercress. An important point is that the menus should be varied so that certain dishes are not served on one particular day of the week for weeks on end: in this recommendation the importance of stimulating the appetite is recognised as a factor to be considered in any dietary.

Obituary

PROF. FRAN JESENKO

YUGOSLAV science, and the University of Ljubljana in particular, has suffered an irreparable loss by the untimely death, on July 16, of Prof. Fran Jesenko, professor of botany at the University of Ljubljana, in consequence of an accident in the Julian Alps.

Jesenko was born near Ljubljana in 1875. He was educated there and in Vienna, where he graduated in 1902. In 1901 he was appointed tutor to two Oriental princes at the Teresianum, the well-known college for boys in Vienna. A similar appointment in the family of Count A. Merveldt, with whom he travelled to Egypt, gave him a good opportunity to study the desert flora. He was afterwards commissioned by the Vienna Botanical Institute to study the flora of Petræa, and at that time he also visited Persia, whilst he was the first Slovene to travel through the Sahara. Upon his return from his travels he studied in Uppsala and Paris. It was during his stay in Sweden that he became an expert in ski-running, and throughout his life he always found time to cultivate that sport.

On his return to Vienna, Jesenko was appointed assistant to Prof. Czermak at the Vienna School of Agriculture, and in 1913 lecturer at the Vienna Botanical Institute. It was during this period that he began to devote himself to what may be described as his life work, namely, the evolving of a fertile cross between wheat and rye. At the fourth International Conference on Genetics, held in Paris in 1911, he was able to report the progress of his experiments in a paper, "Sur un hybride fertile entre *Triticum stativum* et *Seccale cereale*", whilst at the time of his death his research had advanced so far that the next step would have been the cultivation of the new cereal on a fairly large scale at an experimental farm.

Jesenko was corresponding member of scientific societies in Great Britain, America, Tokyo, Leningrad, Uppsala, and Paris. We may quote a few of his early works as follows: "Beziehungen zwischen der Lichtintensität und dem anatomischen Bau der assimilierenden Organe von Wüstenpflanzen" (1907); "Einige neue Verfahren die Ruheperiode der Holzgewächse abzukürzen" (1911–12); "Über das Austreiben im Sommer entblatterten Baume und Straucher" (1912); "Versuche über die Turgenszensdauer abgeschittener Pflanzensprosse" (1910); and "Über Getreide-spezies-Bastarde (Weizen-Roggen)" (1913).

In 1914 he was called up for active service, and during the War suffered seven months' internment in Bohemia, because of his sympathies with the Slav cause and the Allies. After the War, his opportunity came with the constitution of the new Yugoslav State. In 1919, Jesenko was first appointed lecturer, and then professor of botany at the University of Zagreb, and in the following year was transferred to the newly founded University at Ljubljana. Here he had all the hard work, but also the satisfaction, which attends pioneer work. He soon conceived the plan of marking off part of the famous Triglav Lakes Valley as a national park, a plan which, in spite of great difficulties, he succeeded in realising.

On July 12, Jesenko set off to join his students at their headquarters in the Triglav Lakes Valley. It is assumed that whilst stepping aside from the steep path up the Komarcha Crag to look at some plant, his heavy pack caused him to overbalance on the precipitous and treacherous slope. He was found by some tourists a little later, his spine broken. He was removed to Ljubljana Hospital, where he died on July 16.

Jesenko was an able linguist and spoke fifteen languages. He possessed a beautiful singing voice; at one time indeed it seemed doubtful whether he might not choose the career of a public singer. His death will be widely deplored, but most of all by his students, whom he imbued with his own enthusiasm and devotion to his work, whilst all who had experience of his kindness and generosity will regret the premature death of the man no less than that of the naturalist.

MR. HERBERT KNAPMAN

IN Herbert Knapman, registrar of the University of Reading, who died on Aug. 14 at the age of fifty-two years, the lover of music and philosophy and the tireless organiser had long survived the brilliant mathematician who went to Cambridge from Rugby in 1898, was second wrangler in 1901, Smith's prizeman in 1903, and a fellow of Emmanuel College from 1903 until 1909. He joined the staff of University College, Reading, in 1903 as a lecturer in mathematics. If as a teacher he inspired awe of himself rather than love of his subject, the intense thoroughness which was his second nature brought a measure of success, and for a time he was even interested in the technique of imparting knowledge. Nevertheless, the steady transfer of his energies to the field of administration was a congenial development, and although the co-ordination of innumerable details seemed to his colleagues sometimes to be a waste of his intellect, there is no reason for supposing that the services which he performed, especially just after the War and at the time of the foundation of the University, so much better than a man less able could have hoped to do, withheld him from any more valuable work that he might have accomplished. The only work which he did as a mathematician was on the Subject Index of Pure Mathematics for the Royal Society Catalogue of Scientific Papers.

Knapman's lifelong passion was for music, of which he had a wide and expert knowledge. His one published paper described some experiments in which he observed a series of harmonic undertones excited by a tuning-fork; the observations were forgotten until the effect was rediscovered twenty years later, and it is evidence of the extraordinary delicacy of Knapman's ear that while he recorded

that ten of the undertones could be heard easily, Dr. Bond, with the same fork, could distinguish the fifth only occasionally.

In spite of lameness, Knapman was for the greater part of his life a strenuous pedestrian; latterly exertion told visibly on him, and he could not easily resign himself to physical inactivity. When eye-strain, though temporary, threatened further to limit his powers, he became acutely depressed, and the end followed rapidly.

An abrupt manner belied fanatical devotion to the University, and impatience with stupidity was balanced by a ready approval of good work. His judgment of men and affairs was valued not only by his colleagues at Reading, but also throughout the wide circle of educational administration in which he was a well-known personality. The perfection of his routine remains, permanently to strengthen the office with which he was associated, but the wit that lit up suddenly the stormiest or gloomiest of committee meetings and played like summer lightning on the rare evenings when he gave himself up to social enjoyment is lost, except in the memory of those who knew him. E. H. N.

DR. J. STUART THOMSON

THE many friends and old pupils of Stuart Thomson will sincerely regret to hear of his death, at the age of sixty-four years, which occurred suddenly after a short sea trip, at Swansea, on Aug. 28. For many years Stuart Thomson, who was the brother of Sir J. Arthur Thomson, was senior lecturer and demonstrator in zoology in the University of Manchester, and many generations of medical and science students in Manchester had the advantage of his patient and sympathetic teaching. His wide knowledge of his subject—and particularly of vertebrate zoology—gave him authority in his lectures, which impressed those who heard him.

Stuart Thomson studied at Edinburgh and Freiburg, and also under Prof. Studer in Berne, who gave him an interest in the group of Alcyonaria on which in later years he became a recognised authority. He held teaching appointments in biology at Edinburgh and Plymouth, and in 1903 became assistant Government biologist at the Cape of Good Hope. In 1910 he returned, going first to Bristol and then to Manchester.

Stuart Thomson was the author of many valuable papers on the Alcyonaria of South African waters, all of them characterised by his patient investigation and careful description of detail. The last of these papers, published in the *Transactions of the Royal Society of South Africa*, in which the problems concerning the geographical distribution of the South African Alcyonaria are fully discussed, is of great general interest and a very remarkable piece of work.

In his later years Stuart Thomson devoted his spare time to the preparation of an elaborate memoir on the anatomy of the tortoise, of which no complete account has been published since the time of Bojanus.

Stuart Thomson resigned his post in Manchester in 1926, on account of failing health, and went to live with his sister in Cirencester, where he spent much of his time in preparing his book for publication. A few weeks ago he expressed the desire to go once more to sea, and his wish was fulfilled in a five days' cruise, but he died suddenly on landing at Swansea. S. J. H.

WE regret to announce the following deaths:

Dr. J. A. Clubb, formerly curator of the City Museum at Liverpool.

Prof. W. H. Sherzer, head of the Department of Natural Science at the Michigan State Normal College, known for his work in geological survey in Michigan, on July 17, aged seventy-two years.

Mr. S. Williamson Wallace, formerly director of the Egyptian Government College of Agriculture and director of agriculture for the State of Victoria, on Sept. 10, aged seventy-seven years.

Dr. A. Wilmore, formerly lecturer in geography at the Westminster Training College and principal of the Technical School, Colne, author of several well-known textbooks of geography and geology, on Sept. 6, aged seventy years.

News and Views

Forestry and National Economy

SIR JOHN STIRLING MAXWELL, formerly chairman of the Forestry Commission, has an article on "Forestry and National Economy" in the *Empire Forestry Journal* (vol. 2, No. 1, 1932). He confines himself to the work of the Forestry Commission in Great Britain and deplores the economy and cuts, which he admits were inevitable under existing conditions. Sir John himself gives the obvious reason why the heavy non-productive expenditure of the Commission could not hope to escape curtailment in the words: "It is unlikely that absolute continuity in the scale of forestry operations will ever be secured except where the expenditure in the forests is wholly met from the revenue they produce. It will be 30-40 years before this happy state of things can be reached in Great Britain." But he points out that the Forestry Commission can seize the opportunity offered and consolidate the work already accomplished and overhaul methods of organisation. In the dominions, the period at which the forests will pay their way may be reached earlier. In India it has been reached already. In the Crown Colonies, where the form of government is more autocratic, continuity ought to be easy of achievement when once the authorities realise the fatal folly of economising on productive expenditure. This latter point has already been alluded to in NATURE (June 11, p. 845).

IN discussing the present position of the Forestry Commission, Sir John gives a brief summary of the work of the first ten years. £9,000,000 was eventually sanctioned for the work to be carried out during the

following ten years. As a result of the May Report on Economy, the annual sum made available to the Commission was cut down by 50 per cent for the next five years. This cut has been met in two ways: first by reducing the provision of forest workers' holdings to the number absolutely necessary for the working of the forests, and, secondly, by stereotyping the annual planting programme at 20,000 acres or thereby, which will substantially reduce expenditure on acquisition of land. An expanding programme necessitates land acquisition on a large scale. Under a stabilised programme, acquisition can be limited to the replacement of the area actually planted. The reduction in area annually required works out at about 40,000 acres. These changes mean that the machine will take longer to arrive at its goal, but that it will not be thrown out of gear. No labour is to be paid off, and elasticity has been achieved partly by the distribution of the planting work all over the country and partly by the fact that the programme has been an expanding one.

National Research Laboratories, Canada

ON Aug. 10, the new National Research Laboratories of the National Research Council of Canada were officially opened in Ottawa by the Governor-General, the Earl of Bessborough. Among other speakers at the official opening were the Prime Minister of Canada, the Right Hon. R. B. Bennett, and Dr. H. M. Tory, the president of the National Research Council and the National Research Laboratories. A description of the building and the proposed organisation of departments and staff was given in NATURE of Jan. 4, 1930. The building is severely classic in style and closely follows the design of the architect's model reproduced in our article. It comprises four stories and basement, and encloses two large interior courtyards, which give ample light to all laboratory rooms overlooking them. Under each courtyard is an arched exhibition hall. There are three main divisions of research, namely, physics and engineering, biology and agriculture, and chemistry. There is also a division of research information which will be responsible for the publication of the *Canadian Journal of Research*, annual reports, technical reports, and bulletins. In the south-west wing is a series of industrial exhibits. Many delegates to the Imperial Economic Conference were present at the opening ceremony, and the Right Hon. Stanley Baldwin presented a number of portraits of eminent men of science which were given by Surgeon-Capt. Hanson.

National Research Council of Canada

THE Report of the National Research Council of Canada for the year 1930–31 states that although industry has been under a cloud, during the year the demand for scientific assistance addressed to the Council has increased greatly. There are now 29 research committees associated with the Council in the solution of scientific and technical problems which arise in industry, and the annual expenditure is a little more than 550,000 dollars. Five fellowships of 1200 dollars, 22 studentships of 1000, and 35 bursaries of 800 dollars a year have been awarded, and 35 researches conducted in Canadian universities have been assisted during the year. From the summaries of the activities of the associated committees and of the reports on assisted researches, it is evident that Canada is building up a corps of research workers whose influence on the future of her industries is likely to be most important.

New Mount Everest Expedition

A NEW attempt to reach the summit of Mount Everest will be made in 1933. The announcement of the expedition, which appeared in the *Times* of Sept. 3, is made by Admiral Sir William Goodenough and Brigadier-General C. G. Bruce on behalf of the Royal Geographical Society and the Alpine Club respectively. The last expedition was in 1924, when Mr. G. L. Mallory and Mr. A. C. Irvine lost their lives within some two hundred feet of the summit, if they did not actually reach the top. On the same expedition, Col. E. F. Norton and Dr. T. H. Somervell climbed to 28,200 feet. The previous attempts were in 1922, when a height of 27,300 feet was reached, and in 1921, when the expedition was a reconnaissance of the routes. Since 1924 the difficulty in renewing the work has been due to the unwillingness of Tibet to grant permission. Now, however, the Dalai Lama has given consent to a British expedition and arrangements are in active progress. The leader of the expedition will be Mr. H. Ruttledge, late of the Indian Civil Service, who has had considerable experience of mountain climbing in the Himalayas. The office of the expedition will be at the house of the Royal Geographical Society, South Kensington, S.W.7, and the secretary is Mr. J. M. Scott, who was a member of the British Air Route Expedition to Greenland.

New Archæological Periodical

THE new archæological publication *Préhistoire*, of which the first number has just been issued, has been planned on lines differing from those of any archæological periodical now running. Its contents will consist entirely of original memoirs, and it will include neither reviews of books nor current news; while in scope it will cover the archæology and art of the pre- and protohistoric periods, that is to say, from the earliest times up to the foundation of the great empires of antiquity. The articles will be descriptive—these dealing with the latest discoveries—statements of new theory, or syntheses taking a broad survey of facts. A special feature will be the illustrations, which in the case of each communication will be adequate to the requirements of the subject, and, in any event, more ample than could be given in the general run of archæological periodicals. It is hoped that the ampler space and fuller illustration which will be available, will make it possible to include in *Préhistoire* studies of which the publication has been impossible up to now owing to their requirements in these respects. The new journal is edited by M. Raymond Lantier with an international editorial committee, which includes, among others, Comte Bégouen, the Abbé Breuil, Mr. Miles Burkitt, Prof. Bosch Gimpera, Prof. H. Obermaier, and Dr. O. Menghin. The first issue contains contributions by

Dr. Henri Martin on the Solutrian sculpture of Roc, Prof. H. Obermaier on the late Magdalenian art of the Grotte du 'Pendo', near Santander, and a long and very fully illustrated study by Dr. R. Forrer of the prehistoric ritual chariot and its survivals in historic times (see Nature of Sept. 10, p. 404). Not only are the illustrations of each article ample, but they are also of a high quality. The price of Part 1 is 125 fr., but owing to the fact that the size of the parts will be variable, the price is not fixed. The annual subscription, however, is 250 fr. The publishers are Librairie Ernest Leroux, Paris.

Prof. J. W. Gregory

Following the obituary notice of Prof. J. W. Gregory by Sir John S. Flett (Nature, June 25, p. 930) and the letter of appreciation by Prof. Bailey Willis (Nature, Aug. 27, p. 310) we have just received a copy of an appreciation by Mr. F. Chapman, palæontologist to the Commonwealth of Australia, who was a lifelong friend of Prof. Gregory, published in the *Melbourne Age* for July 16. Much of Mr. Chapman's testimony is naturally concerned with Prof. Gregory's activities during the short period (1900–4) when he was professor of geology and mineralogy in the University of Melbourne. Victoria offered many fascinating geological problems ready to hand, and Prof. Gregory took advantage of these for a thorough training of his students in field work. One of his expeditions with a party of students to Central Australia resulted in his writing one of the finest geological essays, "The Dead Heart of Australia".

Prehistoric Persia

Should subsequent investigation confirm the tentative attribution of a date contemporary with Susa I. to the Stratum I. in the mound now under excavation by the American Institute of Persian Art and Archæology a. Damghan in northern Persia, the discovery fully justifies the claim for interest and importance made by Dr. Arthur Upham Pope in his letter to the *Times* of Sept. 12. He states that Dr. Erich Schmidt, field director of the expedition, has found in that stratum beautiful hand-made pottery and copper implements upon which he bases his suggested dating. He regards the lowest levels of the mound upon which the expedition is now engaged as coming very close to the fourth millennium B.C. Further evidence of this extension of the early painted pottery culture will be awaited eagerly. The important structure revealed in Stratum III., dating from about 2000 B.C., is of exceptional interest, not only on account of the singularly rich treasure of objects of high artistic merit in gold, silver, copper, and semi-precious stone, but also for the remarkable burial of a dancing girl which was found in one corner of the building. The body was laid out in dancing pose, with silver rings on the fingers, copper rings in the ears, long coiled armlets, a necklace of effigies of turtles in lapis and silver and a little copper lion, silver tubes, lapis beads, and other objects and ornaments in metal and stone. The mere catalogue of the finds calls up an intriguing picture of the magnificence of this early eastern court, of which, however, the significance will be much enhanced when something more is known of its cultural and artistic affinities.

Mohenjo-Daro Ideographs

A bold and entirely speculative attempt to arrive at the meaning of the pictographic designs on the seals found at Mohenjo-Daro, in the valley of the Indus, is made by Sir Flinders Petrie in the course of a notice of the recently published account of the excavations on this site by Sir John Marshall, which appears in *Ancient Egypt*, 1932, pt. 2. Sir Flinders Petrie justifies his method of attacking the problem by taking the ideographic signs in their primary sense of 'pictures' expressive of ideas, on the grounds, first, that being engraved on stone they escaped transformation and retained their original detail, thus being comparable with the ideographic method of Egypt; and secondly, that the study of official titles and the method of writing them in Egypt has supplied parallels to what may be discerned in India. Thus the recurrence of a number of strokes suggests that parallel to an Egyptian 'Home of Four', 'Five Men', and the like, we have a 'Hall of Four', 'Hall of Six', etc., pointing to a system of naming officials by the number holding office, like the Duumviri, Decemviri, etc., of ancient Italy. There is evidence for this method in Cappadocia. Another set of signs consists of wheels with six or four spokes, that is, chariots and wagons, signifying transport. 'Timber', 'water supply', 'an army', 'game', or 'hunting' are meanings suggested for other symbols, which, in combination with other signs suggesting authority, are interpreted as the designation of officials connected with departments of State; thus, 'Officials of the Registry of Chariots'. Nearly one-half of a hundred symbols are interpreted tentatively on the presumption that they are certainly ideographic signs such as lie at the base of Egyptian, Sumerian, and Chinese writing, but at so early a stage that the forms can mostly be recognised.

The 'Historical Society of Science', 1841

In *Isis* for July 1932, Mr. H. W. Dickinson gives an account of the Historical Society of Science founded in London in 1840 by J. O. Halliwell and Thomas Wright. Halliwell, who was born in Chelsea on June 21, 1820, and died near Brighton on Jan. 3, 1889, was a most remarkable man, and even as a boy had a passion for collecting MSS. He matriculated from Trinity College, Cambridge, in 1837, and before he was twenty years old had written a life of Samuel Morland and edited Sir John Mandeville's "Travels". In 1839 he was elected F.S.A. and F.R.S. The prospectus of the short-lived society for the study of the history of science said that its object was "to render materials for the history of the Sciences accessible to the general reader, by the publication of manuscripts, or the reprinting of very rare works connected with their origin and progress in this country and abroad". The Duke of Sussex became the president of the Society, and on the council were de Morgan, Palgrave, Baden Powell, Gardner Wilkinson, Prof. Robert Willis, and others. But though its start was an

auspicious one, the Society had but a short life and came to an end within a year. Halliwell—or Halliwell-Phillipps as he was called in later life—was a great writer on Shakespeare. He arranged and described the Stratford-on-Avon archives and initiated the movement for the purchase of the site of New Place, Shakespeare's residence there.

Whales Stranded in Scotland

SCOTLAND is favoured by the number of whales and whale carcases which are deposited upon its shores, and although this accident of position involves the expenditure of dealing with unsavoury nuisances, it has its scientific value. Accordingly a memorandum has been addressed to Scottish medical officers of health, sanitary officers, and the like, by the British Museum (Natural History), requesting the co-operation of these local officers in recording the stranding of whales, porpoises, and dolphins. Whenever a whale is stranded upon the British coast, a telegram, followed in due course by a detailed report, is sent to the Museum by the receiver of wreck or coastguard, and the Museum telegraphs to the sender to let him know whether the whole or any part of the whale is wanted, either for purposes of identification or for preservation. In this way much valuable information has been gathered in recent years regarding the cetaceans frequenting British waters and their seasonal movements; and the present memorandum aims at extending the scheme of notification. It states that as a rule a few days' delay does not affect the condition of a stranded whale, that a small whale killed by stranding can lie on a beach for as much as three weeks without giving rise to any serious nuisance and without entailing the slightest risk of infection, and that carcases moored in the water will keep quite well for as long as seven weeks. It is also pointed out that in this matter the British Museum is working in co-operation with the Royal Scottish Museum, Edinburgh, and that an eventual sharing of the specimens between the two museums has been arranged.

Protection of the Grey Seal

THE Fishery Board for Scotland has issued a notice directing the attention of fishermen and others to the provisions of the Grey Seals Protection Act of 1932. By that enactment a close time exists, between Sept. 1 and Dec. 1 inclusive, for the taking of grey seals (*Halichœrus grypus*). Any person taking, killing, or wounding any grey seal within the above-mentioned close season is liable on summary conviction to a penalty not exceeding £5, and any owner, master, charterer, or hirer of a boat, using or permitting his boat to be used for the purpose of taking, killing, or wounding grey seals during the close season, is liable on conviction to a penalty not exceeding £10.

Animal Groups in Philadelphia Museum

REGARDING our comment about the incongruous grouping of small mammals in certain cases in the Museum of the Academy of Natural Sciences of Philadelphia (July 16, 1932, p. 90), Mr. Leigh Mitchell Hodges, public relations director of the Academy, writes to say that the sole purpose of the cases in question was to bring together the outstanding examples of the small mammals common to Pennsylvania and New Jersey. No effort was made to exhibit them in their natural surroundings, the grouping being simply a convenient aggregation primarily for the education of school children. Nevertheless, the introduction of a certain amount of 'environment' might suggest to children the definite association in Nature of species not usually found together, and this possibility is what we had in mind. In the Museum as a whole, as is well known, great progress has been made in the development of habitat groups, the large cases illustrating lions, Kodiak brown bears, Stone's sheep, and Rocky Mountain goats being particularly fine examples of such exhibits. During the present year, groups of musk-oxen and whistling swans have been constructed, and the programme for the future includes cases of the giant sable antelope, African animals at a water-hole, and the giant panda of Tibet.

Hancock Museum, Newcastle-upon-Tyne

THE Council of the Natural History Society of Northumberland, Durham, and Newcastle-upon-Tyne has decided to issue an occasional museum bulletin, with the view of keeping members and associates in closer touch with the activities of the Society and the Museum. The first number of the *Bulletin* contains short paragraphs directing attention to the summer field meetings of the Society, the Museum wild-flower exhibit, and the new arrangement of the Abel Chapman collection of big game trophies and birds of prey. A curious addition to the collections is a hybrid between an English pheasant cock and a white Wyandotte hen, much larger and heavier than an ordinary pheasant, but very pheasant-like in carriage and shape and in the plumage of head, neck, back, and sides. Legs and feet follow the domestic fowl pattern, and the right leg bears a short spur. The bird tasted more of fowl than of pheasant. It is matter for regret that the increase of goldfinches in parts of Northumberland and Durham has attracted the professional bird-catcher, so that the beautiful birds are again threatened with extinction. A strong appeal is made for an increase in membership, so that the good work of this century-old Society may be continued unabated.

B.D.H. Book of Analytical Reagents

A SECOND, revised, and enlarged edition of "The B.D.H. Book of A.R. Standards" has been issued (price 2*s*. 6*d*. net; postage 6*d*. extra) by the British Drug Houses, Ltd., Graham St., City Road, London, N.1. Fifty new substances have been added to the 158 chemicals in the first edition, and the limiting values of the various tests have been stated at the head of each section in the form of a table which represents the maximum permissible limits for the various impurities. We may remind readers of NATURE that the letters A.R. (replacing the unsatisfactory description "Chemically Pure", or C.P., an unattainable ideal) denote analytical reagents of controlled and specified purity, and users of such reagents will thus be able, by means of this monograph, to judge what impurities may possibly be present and in what amounts. It is clear that, with improvement in analytical chemistry, some of the specifica-

tions may be given still further precision in future editions. The entry under copper oxide, for example, on p. 62, which returns nitrate, carbonate, and organic matter as "nil" on the basis of a rather crude test, is obviously capable of revision, and other cases will no doubt suggest themselves to the reader. For routine work, as distinguished from research, these specifications will be of considerable value, and the book will be found useful in all analytical laboratories.

Refractories

We have received from Messrs. John G. Stein and Co., Ltd., of Bonnybridge, Scotland, an interesting catalogue of refractory materials, dealing with various grades of firebricks, silica bricks, cements, retorts, etc. This firm has an output of one million refractory bricks weekly. All the clays required are obtained from the firm's own mines, and throughout the process of manufacture every factor is scientifically controlled, thus ensuring uniformity of products. The catalogue, which is well produced and illustrated in colour, gives a number of useful tables and formulæ, together with lists of the principal uses of the products. It contains some phase rule diagrams, for example, of the forms of silica and of the system $SiO_2 - Al_2O_3$, and a glossary of terms relating to silica and fireclay refractories. Special shapes will be made when required, the manufacturers being willing to cooperate in producing a satisfactory result in such cases. This catalogue is of a type which deserves every commendation, since it indicates a close cooperation of scientific and technical knowledge and a realisation of the importance of research in maintaining the quality of the products and in making progress in new directions, which are most encouraging.

Non-Ferrous Metals Research

The twelfth Annual Report of the British Non-Ferrous Metals Research Association shows that in spite of the industrial depression, progress has been well maintained. With a Government grant of £8000, the total income has been brought up to more than £25,000, proving that the industry has found the work of the Association of increasing value. In June 1931 the new headquarters in Euston Street, London, N.W.1, were opened, and visitors have been able to see how well the limited space available has been utilised for experimental work, and for the equally important work of collecting information and making it accessible to members. A study of the methods of the Association in this field would provide lessons for other research organisations, especially for such as have to make their results intelligible and serviceable to manufacturers, many of whom may have no adequate scientific staff to interpret the conclusions of the research workers. The subjects under investigation include many which are of interest to workers in pure science as well as to industrialists, and the results of these are usually communicated to a scientific society after they have been circulated to members. Whilst several of the investigations are now carried on at headquarters with the help of the equipment recently installed there, much research of importance is also in progress for the Association at the National Physical Laboratory, the Research Department at Woolwich, the University of Birmingham, and elsewhere.

Organisation of Living Things

In a short article in *Scientia* (Aug. 1932, p. 84) Dr. J. Needham discusses the problem of organisation and its place in the biological thought of the present day. Organisation is a property of all matter, and the organisation of living things is at one with material organisation, even if on a grade of its own. It is not something which controls or directs the material system, but is bound up with, and inseparable from, the organised matter itself. From this point of view organisation in the biological sense is something integral with the rest of scientific data, which science can take into account; and it will probably make necessary a widening and stretching of the classical concepts of physics and chemistry rather than an abandonment of them, so that a new mechanism will be evolved to include the modes of action and the organising relations found in living systems. Herein lies the central problem of biology, and biology will make progress only when, as has happened in physics and chemistry, attention is given to the theoretical principles which underlie and would co-ordinate the multifarious studies and researches of the field and the laboratory.

International Co-operation among Agricultural Brain-workers

Under the above title the Czechoslovak Academy of Agriculture has recently published in book form—in French, German, English, and Czech—the proceedings of a meeting of its corps of foreign members held at Prague on June 3, 1931, a matter which has already been referred to in this journal (**128**, 597; 1931). On this occasion detailed proposals were put forward by Dr. Reich, the secretary-general of the Academy, for furthering the international co-ordination of scientific and intellectual effort as applied to the agricultural domain. Among these was the original suggestion that an international 'Nobel prize' of the annual value of 1,000,000 Czechoslovakian crowns (approximately £8333) should be founded and awarded for the best piece of scientific work in agriculture. In this way it is expected that two important results will follow. In the first place, definite financial recognition can be awarded to investigations of outstanding merit. In the second place, an annual award of this character cannot fail to exercise a great moral and intellectual stimulus on the future development of agricultural science. An international committee, consisting of eighteen members, has been appointed to work out the details of the scheme and to collect the capital sum needed. In view of the fact that the welfare of industry is intimately bound up with that of agriculture and that in the future both must stand or fall together, it should not prove an impossible task for the nations to endow such a 'Nobel prize' for agricultural research.

British Association of Commercial Seed Analysts

The seventh Conference of the British Association of Commercial Seed Analysts was held on July 21 at

the National Institute of Agricultural Botany, Cambridge. The president, Mr. A. E. Birks, stated in his address that members are continuing to avail themselves of the facilities afforded by the Association, and during the year a number of interesting experiments were carried out by members working together. In one case, tests were made on a particularly difficult sample of asparagus kale in an endeavour to arrive at an equable result. The wide divergence in results obtained proves that there still remain factors governing the germination of this seed which are not fully understood. Mr. Harding gave an address on the comparison of soil and laboratory tests. He considers that soil tests properly carried out are of real value in estimating the maximum percentage of plantlets that can be obtained under field conditions. In some instances, when working upon new seeds, results from the laboratory and the soil tests are identical: greater differences occur when old seed is being tested. Finally, soil tests are certainly helpful when made in conjunction with the laboratory, as they assist in revealing discrepancies. The following officers were elected for the coming year: *President*, Mr. E. B. Wallace; *Vice-President*, Mr. A. E. Birks; *Hon. Secretary and Treasurer*, Mr. F. H. G. Neale, "Emmandee", Hawthorn Gardens, Reading.

Annual Report of the Ministry of Health

THE thirteenth Annual Report of the Ministry of Health, 1931–1932 (H.M. Stationery Office. 5*s*. net), recently issued, is in the main a record of the more important business transacted by the Ministry during the year, and does not cover matters of routine or detail, the Annual Report of the Chief Medical Officer of the Ministry being published separately as in previous years. Allusion is made to the British Postgraduate Hospital and Medical School, now in process of formation, for which a grant of £250,000 had been previously contemplated, but for which Parliament will now be invited to contribute a maximum grant of £100,000 in view of the exigencies of the time. The National Radium Trust has made further purchases of radium, and now owns a little more than 17 gm. Local authorities have been active during the year in the sewering of their areas, and loans sanctioned during the year amounted to nearly 7¾ million pounds. Other subjects dealt with in the Report fall under the main heads of public health, housing and town planning, local government and finance, poor law, and national health insurance.

Library of Educational Films

THE Empire Marketing Board has published a new edition of its film library catalogue, and copies are obtainable free on request from the Board, 2 Queen Anne's Gate Buildings, London, S.W.1. A great variety of films illustrating different aspects of scenery, natural history, and economic activity is now available. These cover most parts of the Empire. An important addition to the list is a series of class-room films, which are intended for the use of teachers rather than for general circulation. There are about forty of these films, some of which are travel surveys, while others deal with such subjects as canals, irrigation, cotton, wool, water power, or social life. All the films are available free for approved displays at which there is no charge for admission. Carriage must be paid by the borrower.

Cancer Mortality in the United States

DEATHS from cancer have increased alarmingly throughout the United States of America in the past year and a half, in the face of extremely favourable general health conditions. Science Service, of Washington, D.C., notes, under date Aug. 9, that figures compiled by the Metropolitan Life Insurance Company upon its industrial policy holders show a rise of 7·4 per cent in 1931, and for the first half of 1932, a further rise of 9·5 per cent over the rate for the like part of last year: the average rise in the period 1919–1930 was 1·5 per cent a year. Although official mortality statistics are not yet available for any large part of the country, the provisional reports are said to substantiate the Metropolitan figures.

Announcements

MR. WILFRED TROTTER has been appointed a member of the Advisory Committee on the Administration of the Cruelty to Animals Act, 1876, in succession to Sir Arthur Keith, who has resigned.

DR. JAMES LAW BROWNLIE has been appointed by the Secretary of State for Scotland chief medical officer of the Department of Health for Scotland in succession to the late Dr. John Parlane Kinloch.

THE annual exhibition of the Professional Photographers' Association was opened at the Princes Galleries, Piccadilly, London, W., on Sept. 5, and will remain open until Sept. 29. The exhibits comprise industrial photography as well as portrait work.

DR. HAROLD MOORE, who has for many years been director of metallurgical research at the Research Department, Woolwich, has been appointed, as from Oct. 1, director of the British Non-Ferrous Metals Research Association, to succeed Dr. R. S. Hutton, who has been elected to the new Goldsmiths professorship of metallurgy at the University of Cambridge.

APPLICATIONS are invited for the following appointments, on or before the dates mentioned:—A lecturer in mechanical engineering at the Swindon Technical College—The Director of Education, Education Office, Clarence Street, Swindon (Sept. 24). Inspectors for the purposes of the Diseases of Animals Act, 1894–1927, in the Ministry of Agriculture and Fisheries—The Secretary, Ministry of Agriculture and Fisheries, 10 Whitehall Place, S.W.1 (Sept. 26). An assistant lecturer in engineering and a lecturer in production engineering at the County Technical College, Wednesbury—The Director of Education, County Education Offices, Stafford (Sept. 29). A lecturer in pure mathematics at the Wimbledon Technical College—The Principal, Wimbledon Technical College, Gladstone Road, S.W.19. A science master (chiefly physics) at the Prince of Wales' Indian Military College, Dehra Dun, United Provinces, India—The Secretary, Military Department, India Office, London, S.W.1.

Letters to the Editor

[The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, nor to correspond with the writers of, rejected manuscripts intended for this or any other part of NATURE. *No notice is taken of anonymous communications.]*

The Late Geological History of British Somaliland

DURING an expedition to explore the geology of British Somaliland, extending to 19 months spent there in 1928–30, much of the country was seen, with the possibly important exception of the coastal strip east of Berbera. It is hoped to publish the geological and palæontological results in due course, and specialists are now working out the fossil collections. The following details noted incidentally may help to supplement Dr. Parkinson's account of the late climatic changes.[1]

A most instructive district is the Bihendula-Dagah Shabell-Daban area[2] (within 40 km. south-south-east of Berbera), where the following succession was found.

1. *Daban Conglomerate*: Some buff shales and conglomerates with boulders and pebbles of Auradu Limestone (Lower Eocene); 111 m. thick in the Biyo Gora Section. In the Rhabka Hills, 6 km. farther east, it includes flint bands and a silicified band with a species of freshwater gastropod, ostracod marls, and fossil wood; thickness at least 270 m. The age is not at present known: it forms the top of the 2300 m. thick Daban freshwater series, which has an intercalation of fossiliferous marine Middle Eocene beds near the base. During its formation, a fault cliff appears to have existed south of the great east-west Dagah Shabell fault, whence fell enormous masses of Auradu limestone, including that of Agagwein, 1100 m. long, the Leopard Rocks, 190 m. long, and many of lesser size; these are embedded in the Daban Conglomerate.

2. *Posthumous Faulting* in the Gulf of Aden trend then took place along the Dagah Shabell fault and affected the Daban Conglomerate.

FIG. 1.—Terraces at Dagah Shabell, British Somaliland, looking south-west. Altitudes in metres. Motor truck by point marked 470 gives the scale. Golis Range in far distance.

3. *The Older Boulder Beds*, largely of Auradu limestone, were next deposited over the area, the material being derived from the high ground to the south. Traces of them are now found up to an altitude of 594 m. at Daghani (east of Bihendula), where one patch lies undisturbed across the Dagah Shabell fault. Immediately south of Dagah Shabell they are better preserved at rather lower levels (Fig. 1, at 528 m.).

4. *Erosion*: A drainage system independent of the underlying solid geology was then established on this gravel-covered area, and during what must have been a long-continued wet period almost the whole of the Older Boulder Beds were eroded from the Bihendula–Daghani area, and the underlying strata deeply cut into by several tugs, which flow almost due north, in a most spectacular manner. Across the strike and against the dip of these beds, which is steadily about 18° south, the superimposed Daghani Tug has cut narrow gorges through three hard Jurassic limestones, 244 m., 103 m., and 80 m. thick respectively, separated by two shales 250 m. and 113 m. thick (the outcrops of which are now occupied by strike valleys), through the Adigrat (? Triassic) Sandstone, 200 m. thick, the Archæan Igneous and Metamorphic basement (in which the narrow gorge is up to 60 m. deep), and, across the fault, through the concrete-like Daban Conglomerate. The Bihen Tug, at Bihendula, has cut a very similar course. The Biyo Gora Tug has cut a vertical-walled gorge only some 10-20 m. wide through the hard and massive Auradu Limestone of the Ali Wein Range (Fig. 2). These gorges were not cut along fault lines.

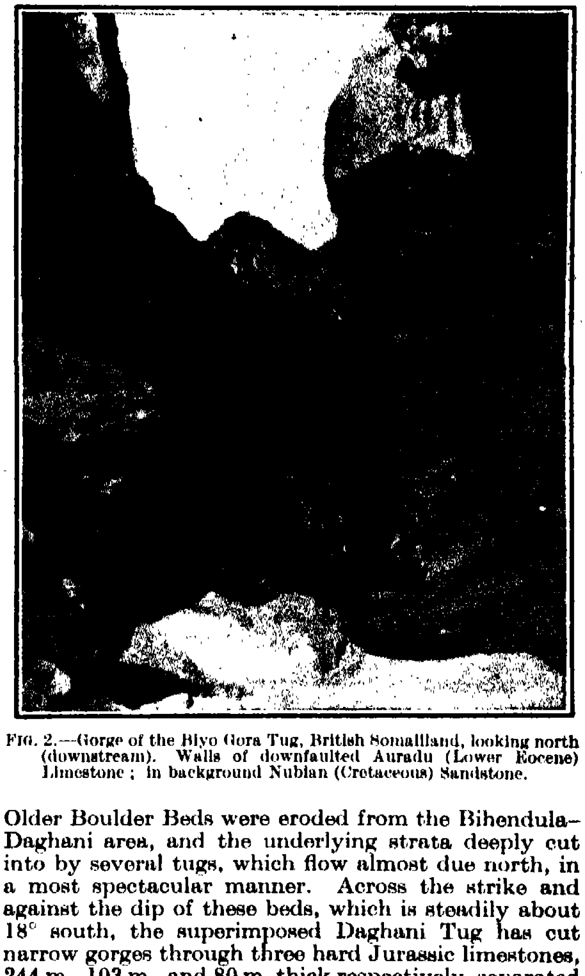

FIG. 2.—Gorge of the Biyo Gora Tug, British Somaliland, looking north (downstream). Walls of downfaulted Auradu (Lower Eocene) Limestone; in background Nubian (Cretaceous) Sandstone.

5. *The Younger Gravels* were next deposited in the valleys (Fig. 1, at 470 m.). These are mainly of Archæan igneous pebbles, but contain some of Auradu Limestone, and are locally largely made up of re-worked Nubian Sandstone and Shabell Beds (Cretaceous). A small tug cut in the Nubian Sandstone was found at Dagah Shabell completely infilled with Younger Gravel, and so not functioning in the present drainage system. During this period were deposited curious nests of Archæan boulders, two of which were found 4 km. and 8 km. respectively south-west of

Dagah Shabell. These boulders comprise an assortment of granitic types and are well rounded; the largest measured about 5 m. × 3 m. × 2 m., and must weigh some 70 tons.[3] The nests are not found in the present-day tugs but on the gently undulating gravel plain. The boundary of the nearest Archæan outcrop lies 11 km. and 7 km. respectively to the south-west.

6. *Erosion* of the Younger Gravels followed to some extent, but much is still left.

A thickness of 45 m. of gravel was measured resting on the Daban Conglomerate at one point, but it is uncertain to which phase this and the gravel cover over the Daban area should be referred.

Phase 6 may be that existing at the present day; the intermittent erosion now taking place would probably be adequate to produce the observed effects. A measure of the amount of erosion since the deposition of the Daban Conglomerate is given by the remnant of the Auradu Limestone cliff from which, if I am right, fell the great masses of limestone now found in that conglomerate on the north side of the Dagah Shabell fault. The three remaining fragments are seen in the Auradu Hills, 11 km. south of the Dagah Shabell fault, and rising perhaps 100 m. above the plain.

Evidence from the coastal district shows that various changes in the level of the land had meanwhile been taking place. At Dubar, 12 km. south of Berbera, at an altitude of 200 m. were found fossils which proved to be of an age not greater than Pleistocene, indicating a poorly marked raised beach. A series of limestone knolls 3-4 km. south-west to south-east of Berbera lie at altitudes of between 50 m. and 85 m. They are fossiliferous, but the hard limestone is much cut and polished by the sand-blast of the Kharif (south-west monsoon), and no fossils were collected. However, an older collection appears to have been made from here, and the fauna is again not older than Pleistocene, indicating a second raised beach. At Berbera is a third, well-marked, raised beach, at a level of 8 m. A correlation between raised beaches and gravel terraces was not possible, since in no case were the two found together: further search may remedy this.

Along the coast between Zeila and Bulhar, and again somewhat inland east and south-east of Berbera, are sand dunes of limited extent. In the latter area they are often of a reddish colour and clearly derived in part from the Nubian Sandstone on which they sometimes rest. They probably belong to the present-day period.

My thanks are due to the Somaliland Petroleum Co. Ltd. for permission to publish this note.

Molecular Weights of the Blood Pigments of *Arenicola* and of *Lumbricus*

IN a letter to NATURE of June 8, 1929, p. 871, one of us directed attention to the fact that all stable native proteins may, with regard to molecular weight, be divided into two large groups: the hæmocyanins with molecular weights of the order of millions, and all other proteins with molecular weights from about 35,000 to about 200,000. Among the proteins considered in that letter were three respiratory pigments, namely, the hæmoglobin of the vertebrates with a molecular weight of about 68,000, and two different hæmocyanins—that from the blood of *Helix*, possessing a molecular weight of about 5,000,000, and that from the blood of *Limulus*, of about 2,000,000.

We have recently had the opportunity to study the hæmocyanin from the blood of *Octopus* and have found it to be very different from the two hæmocyanins just mentioned, although of about the same molecular weight as the *Limulus* hæmocyanin. The sedimentation constant is higher and the shape of the molecule less asymmetrical. A few preliminary runs on chlorocruorin from the blood of *Spirographis* have further indicated that this respiratory pigment, like the hæmocyanins, has a molecular weight of the order of millions. With regard to the active group of the molecule, chlorocruorin is more allied to hæmoglobin than to the hæmocyanins, its characteristic element being iron and not copper. The fact that an active group containing iron and of semi-hæmin type is here associated with a protein carrier of about the same mass as the hæmocyanin molecule has led us to consider the possibility that there might exist other respiratory pigments of molecular mass of the order of millions but with the hæmin group of the hæmoglobin of the vertebrates.

If such respiratory proteins exist, they would most likely occur in the blood of the lower animals. Now, it is well known that several worms and molluscs have red blood. As a rule, the respiratory pigment of these animals is not in corpuscles but is in solution in the blood. This red protein has hitherto been considered as a form of hæmoglobin. J. and H. Barcroft have made a very thorough study of the absorption spectrum and of the affinities for oxygen and carbon monoxide of the blood pigment of *Arenicola*.[1] They arrive at the conclusion that the pigment is "of the same general type, but different in detail from that of human blood". We quite agree with these authors that the spectroscopic evidence as well as the behaviour of the pigment towards oxygen and carbon monoxide prove that its active group closely resembles hæmin, but this does not necessarily mean that the mass and the chemical properties of the protein part of the molecule are the same as those of the hæmoglobin of the vertebrates. The fact that it is not in corpuscles but dissolved in the blood like hæmocyanin and chlorocruorin seemed to us very significant, and suggested that this pigment was the predicted high-molecular hæmoglobin-like protein. An ultra-centrifugal study has fully confirmed this supposition.

Blood from *Arenicola marina* which had been kept in ice for about two days was diluted with a 1 per cent solution of sodium chloride and the sedimentation velocity of the molecules measured at 20°. It was found to be beautifully homogeneous with regard to molecular mass, and gave a sedimentation constant of 60×10^{-13}. This is not far from the value of the sedimentation constant of *Octopus* hæmocyanin, namely, 45×10^{-13}, and from that of *Helix* hæmocyanin, namely, 98×10^{-13}, but is of quite a different order of magnitude from the sedimentation constant of the vertebrate hæmoglobin, which is $4{\cdot}4 \times 10^{-13}$. The molecular weight of the blood pigment of *Arenicola* is therefore of the order of millions.

For the sake of comparison, a determination was also made with blood from *Lumbricus* collected immediately before beginning the run. The sedimentation constant of the respiratory pigment was found to be 68×10^{-13}. It is possible that the *Arenicola* blood used for the determination of the sedimentation constant may have decomposed slightly during the time between collecting and centrifuging it, and that therefore the value of the sedimentation constant of quite

fresh *Arenicola* blood is somewhat higher. But even if allowance be made for this slight uncertainty, we believe that there remains a real although small difference between the sedimentation constants of the blood pigments of *Arenicola* and *Lumbricus*.

The fact that not only the hæmocyanins but also other respiratory pigments in the blood of the lower animals have molecules of enormous mass seems to us very remarkable. It would be of considerable interest to try to find out at what stage of evolution the normal hæmoglobin appears, and whether its existence is exclusively connected with the formation of blood corpuscles. Perhaps hæmoglobin with its comparatively low molecular weight is strictly limited to the blood of the vertebrates, and the very high molecular weight respiratory pigments to the blood of the invertebrates. A study of the molecular weights or the sedimentation constants of the blood pigments throughout the animal kingdom might serve to throw light upon the relationships of the various classes of animals and upon their relative age.

The Limiting Mobilities of some Monovalent Ions and the Dissociation Constant of Acetic Acid at 25°

MACINNES, Shedlovsky, and Longsworth [1] claim to have obtained accurate figures for the limiting mobilities of certain monovalent ions, *inter alia*, K^+, 73·50; Na^+, 50·10; H^+, 349·72; Cl^-, 76·32; CH_3COO^-, 40·87; and they refer to the discrepancies between these and the older figures compiled by Noyes and Falk.[2] We would point out that all these constants, except that for the acetate, were determined by us some time ago,[3] and were based on the use of the Ferguson and Vogel method [4] for extrapolation to infinite dilution and a value of 0·490 for the cation transport number for potassium chloride; our figures are K^+, 73·4; Na^+, 49·8; H^+, 348·0; Cl^-, 76·4, that for the hydrogen ion being based on conductivity measurements of iodic, hydrochloric, and benzenesulphonic acids in dilute solution in silica cells.

We have recently carried out conductivity measurements on sodium and potassium acetates and have corrected the results for hydrolysis by a method which is of general application; our figure for the mobility of the acetate ion is 37·85. New determinations of the conductivity of acetic acid over the concentration range $0{\cdot}0001 - 0{\cdot}01N$ in silica cells of the Hartley and Barrett type gave the value of $1{\cdot}776 \times 10^{-5}$ for the true or thermodynamic dissociation constant of this acid. This is much higher than the figure $1{\cdot}753 \times 10^{-5}$ obtained by MacInnes and Shedlovsky.[5] Full details of these results will be published in the near future.

Structure of Polished Solids

IN consequence of the recent communication of R. C. French [1] on the structure of polished surfaces—investigated by high-speed electrons—and the fact that at the same time W. Boas and E. Schmid,[2] using Laue reflection diagrams, come to rather different conclusions, it seems desirable to mention some of the results, obtained on different experimental lines and published in Holland about a year ago.[3] These latter results suggest that polishing should be considered primarily as a very fine process of abrasion of the suitably prepared surface, accompanied by a levelling of surface lamellæ (or micellæ), the first step in this direction already being made when grinding the specimen (plastic deformation in the surface layers).

Delicate polishing leads, *inter alia*, to a dragging of minute particles along from the surface, the size of the detached aggregates of atoms ranging mainly in the case of most common hard metals at room temperature from about three to about thirty atoms.[4] Now it is well known that, in the region of dimensions of this size, the properties of aggregates show an exceedingly large variation with particle size. One must therefore consider the process which yields such aggregates—in spite of their very small dimensions—as still being essentially different from a 'molecular' process.

The amicrons [5] concerned may be made discernible ultramicroscopically by means of suitable physical development (Daguerre, Houllevigue, Stern, etc.). A part of the originally detached particles, however, fills up existing pits in the surface and recombines with it (by a process of adhesion, as well established in previous work of the late Sir G. Beilby). The mechanism of polishing always occasions the formation of a surface film ('skin') which largely differs in properties from the underlying material ('core').

The polishing of glass meets with a complication as a consequence of the presence of a eutectic rich in alkali embedded in a framework rich in silica. The soft alkali is the more easily removed part; [6] moreover, that part of the detached particles which is richest in silica—being chemically inactive and fitting easily into the surface pits—adheres best to the surface. In this way a more resistant form of surface-film may be produced.

According to H. Zocher and K. Coper,[7] even such delicate working as the one-directional rubbing of a very hard body, such as quartz, with, for example, a piece of cotton wool, gives rise to a surface anisotropy, as a consequence of deformation, ranging to depths below the surface which are large in comparison with molecular dimensions. Heating may occasion a disappearance of the surface anisotropy, depending on the time of heating and the maximum temperature applied, in a way which agrees with general rules as already given some time ago by W. Reinders and L. Hamburger,[8] who investigated the microscopical, ultramicroscopical, and electrical behaviour (resistance) of thin metal and salt films under varying conditions of film thickness, film backing, mode of preparation, temperature, effect of catalysts and chemical agents.[9]

The carefully polished surface films of crystalline materials—prepared and kept at a temperature far below the melting point—consist of lamellæ of levelled crystallites of non-microscopic dimensions which show a frequency distribution of particle size. These films ordinarily pass into the core material via a transition layer of relatively great thickness, along which the structure and texture show a *continuous* change.[10] The nature of polished surfaces is, more-

over, complicated as a consequence of its general physical metastability;[11] further, through the adsorption of foreign substances, the occasional occurrence of embedded abrasives (rouge, etc.), and the presence of more or less disturbed boundaries of contact between the minute particles. The importance of the latter factor is, of course, more pronounced than in the case of relatively coarse-grained materials, where the intergranular surface of contact is only a relatively small one.[12]

Mechanism of the Action of X-Rays on Living Tissues

CHEMICALLY, nothing definite has been known on the action of X-rays. This lack of knowledge has led to their use where the benefits of X-irradiation are problematic. X-ray dosages, too, must be set empirically owing to inability to measure in any way their immediate effect on the cells. Even after waiting a week or ten days, only the gross effects can be determined.

From certain theoretical physical considerations based upon cellular oxidations and reductions of the redox type, it occurred to me that, when tissue was irradiated with X- or γ-rays, a definite amount of hydrogen should be evolved. This hydrogen should be rapidly diffused through the tissue walls, and thus could be measured.

A detailed explanation of the hypothetical assumptions made previous to this experiment will follow as soon as certain quantitative data are available. Such data, I hope, will give a criterion for determining the advisability of using X-rays, as well as definite information on which to base the dosage.

In this experiment a micro-respirometer was constructed, having by far the greater volume of air space concentrated in the middle of a tube. On either side of this air space stop-cocks were placed so that the whole could be dismounted for analysis. The respirometer was used to make sure that the tissues employed were alive, and air was used throughout. In the first case, a small piece (about 0·25 c.c.) of normal human rectus abdominus muscle was placed in Ringer's solution, and irradiated in the respirometer for 45 minutes with X-rays. A tungsten target and a dosage of 90,000 r. units (20 ma. 75 kv.) were used. The gases in the respirometer were then analysed and found to contain 1·6 per cent hydrogen, by volume. In the second and third cases, primary carcinoma of the breast were used, and 1·03 and 1·27 per cent hydrogen were evolved respectively. In the fourth case, primary carcinoma of the rectum showed 0·83 per cent hydrogen. The experimental error in the determination of hydrogen was less than 0·05 per cent by volume. As the volume of gas contained in the micro-respirometer was approximately 150 c.c., 1 per cent hydrogen would be equivalent to 1·5 c.c.

The amount of tissue used in each case was of the same order of size, but was not weighed or measured, as the important preliminary consideration was to establish the fact that both normal and pathological tissues actually gave off hydrogen during X-irradiation. γ-Rays were not used, but should have a similar effect. Controls were then run as follows: (1) the empty respirometer was irradiated to determine whether any hydrogen was given off from the glass; (2) Ringer's solution was irradiated; (3) and (4) normal and pathological tissue were allowed to respire freely. The gases in each case were then analysed. All the controls were found to be negative for hydrogen. Of course sodium hydroxide was used to absorb the carbon dioxide produced. This was irradiated in (2) above.

The tissues were all killed after about 25,000 r. units. A control was run on muscle tissue that had been killed by asphyxiation, and no hydrogen was evolved after a dose of 90,000 r. units had been used. This, of course, is significant, inasmuch as the hydrogen comes only from the living tissues. Later quantitative measurement, using normal and pathological tissues from the same area, should prove especially enlightening in view of the relative rates of metabolism. The effect of smaller doses of X-rays, and ascertaining which wave-lengths give the maximum effects, should aid in determining exact X-ray dosages.

The fact that hydrogen is removed from the scene of action in tissue metabolism, I believe, is largely responsible for the killing, or at least reducing, the vitality of the cells. Just how this affects them can probably best be shown through oxidation relationships. This will be discussed in a later paper. Regardless of the precise method of evolution of hydrogen, the fact remains that it does come from somewhere within the tissues.

I wish to express my indebtedness to Dr. N. Rachevsky for his continued help throughout this work, to N. A. Ziegler for making the hydrogen analyses, and to George V. Le Roy for certain physiological data resulting in this experiment. (Preliminary Report.)

Radiographs of Insects

FINDING no record that radiographs of insects were ever made, last summer we took several hundred radiographs of some forty different species of insects. The X-ray tube, constructed in the laboratory, was of lithium glass, and furnished with a very thin window allowing rays of sufficient softness to be used. 3500 volts was the lowest potential with which this tube could be run, and with this potential the venation of wings was shown very distinctly. During the whole work, potentials ranging from this lower limit to 15,000 volts have been used, according to the size of the insect. The insect was placed directly on the photographic film, which was of the type manufactured by the Eastman Kodak Company for dental work.

As an example of the type of radiographs obtained, a reproduction of one showing a *Hydropsyche* larva is given in Fig. 1.[1] The coiled structure is the Malpighian tubules, while the long, narrow, longitudinal

bands are the silk glands. The Malpighian tubules are shown pure white, indicating that they contain chemical elements of comparatively high atomic weight. Excretion of ingested inorganic salts may be indicated, inasmuch as radiographs of different specimens show various degrees of opacity, from no delineation to complete whiteness of the image.

The digestive system and the tracheal tubes are usually the most pronounced structures seen in the

FIG. 1.—Radiograph of *Hydropsyche* larva. ×3.

radiographs. The digestive tract often contains opaque food matter. In insects having a complicated digestive tract, such as the cricket, the detailed structure of the fore and hind gut stands out distinctly. The musculature and the architecture of the chitinous exoskeleton are well brought out. The fat body often exhibits a granular structure, due presumably to the storage of insoluble excretory products containing a chemical element of comparatively high atomic weight. The reproductive organs are not shown well, except that the male accessory reproductive apparatus and, occasionally, the testes themselves and their ducts are visible (water strider). The venation may be brought out beautifully. As an aid to morphological work in the classification of insects, certain details may be brought out which would obviate the dissection of the insect. An important usage may be in physiological studies, especially of digestion and excretion.

We have received invaluable assistance from Dr. S. I. Kornhauser, of the University of Louisville, during this work, for which we express our gratitude.

Petroleum Bacteria and the Nutrition of *Psilopa petrolei*

IN a recent letter to NATURE,[1] Messrs. Lipman and Greenberg have described a coccus or cocco-bacillus occurring in petroleum obtained from a Californian oil well 8700 ft. in depth, and have stated that it has the power of oxidising petroleum with the production of carbon dioxide. This is an interesting addition to the list of micro-organisms which have been recorded as capable of decomposing paraffin hydrocarbons.[2]

The record is, however, of particular interest by reason of its possible connexion with the nutrition of the petroleum fly, *Psilopa petrolei* (Diptera, Ephydridæ). In 1930, I published[3] an account of the biology of this extraordinary insect, in which I described and illustrated the mid and hind gut of the larva as containing great numbers of a cocco-bacillus. My experiments showed that the fly larvæ, which had previously been supposed to feed on the paraffin itself, were unable to go through their development in the absence of extraneous animal matter such as the bodies of small insects; these being frequently trapped in the pools of crude oil where the larvæ live. The experiments did not, however, prove that the larvæ were incapable of deriving *any* nourishment from the oil, which is constantly swallowed, and it was indeed suggested that the bacteria in the proctodæum might be concerned in nutrition, either serving directly as food or by the production of some available substance from the petroleum. This hypothesis appeared all the more probable in view of the great abundance of larvæ in some of the pools contrasted with the apparent scarcity of trapped insects which could be used as food.

In 1931, I obtained some specimens of oil from the Santa Fe Oil Field of southern California, some samples being taken from exposed oil pools, others direct from the wells. These specimens were kindly examined by Mr. J. H. V. Charles of the Division of Biochemistry of the London School of Hygiene and Tropical Medicine. Large numbers of bacteria-like bodies were observed in all samples, although more abundant in those from the exposed pools. First attempts to culture these organisms in pure paraffin hydrocarbons were unsuccessful, but it has now been found possible to grow them in Söhngen's hydrocarbon-ammonium chloride medium at 32° C. The organism first obtained differs from that found in the alimentary canal of *Psilopa*, and from that described by Lipman and Greenberg, in that the bodies are rod-shaped (or fusiform) rather than cocco-bacillary in form. However, Mr. Charles now informs me that, after continued incubation, the cultures show numerous bodies cocco-bacillary in form and exactly similar in appearance to the organism found in the gut of *Psilopa*, although the original larger fusiform bodies are still present in abundance. As yet, nothing has been ascertained as to the metabolism of these bacteria, but work on the subject is being continued, and it is hoped that before long some knowledge as to their mode of life will be forthcoming.

It appears that such organisms are by no means universally present in natural oils, although, according to Söhngen, organisms (bacterium, mycobacterium, micrococcus) capable of oxidising paraffin are easily obtainable from soil. While in Trinidad recently, I obtained a number of fresh petroleum samples from oil wells of varying depth in the neighbourhood of Apex, San Fernando, but in no case were any bacteria or other organisms found.

The abundance of micro-organisms in Californian oil fields may conceivably have some connexion with the ability of an insect to colonise this particular environment—an achievement, so far as is known, unparalleled elsewhere.

Diffraction of Electrons in Mercury Vapour

Two years ago, while investigating the angular scattering of electrons in mercury vapour, I found well-marked diffraction effects.[1] In that investigation, results were obtained over an angular range of 18°-126°, and for velocities of the primary electron beam between 8 volts and 800 volts. It was later announced that the work was being extended to larger angles and to other vapours.[2] The apparatus has now been modified to enable results to be obtained for angles up to 175°.

In Fig. 1 some typical results for mercury vapour are shown. An interesting feature of the new results

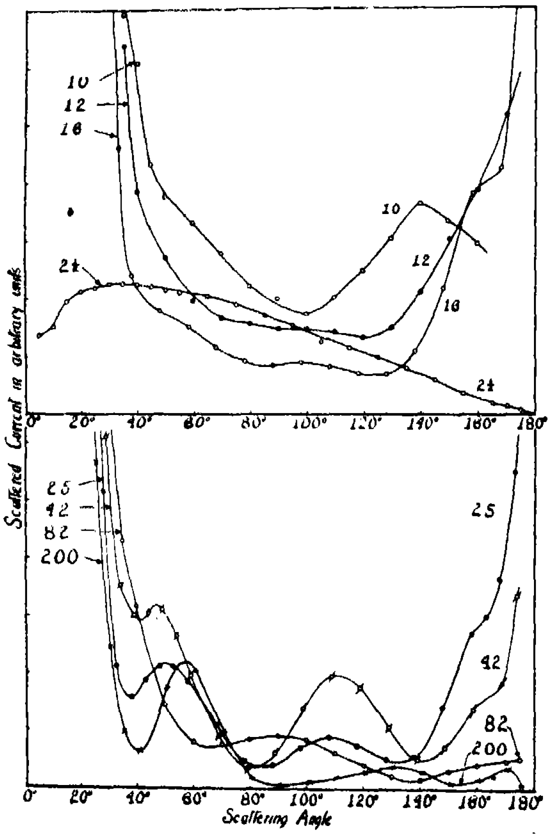

FIG. 1.

is the strong backward scattering of electrons having energies between about 50 volts and 10 volts. This feature has also been found to occur in the rare gases by Ramsauer and Kollath,[3] and in argon by Hughes and McMillen.[4]

In addition to the results given in Fig. 1, curves have been obtained for a number of intermediate voltages. As these curves merely show transition stages between the curves reproduced here, they have been omitted in this preliminary report. A full account of this work will be published shortly, and in the meantime other vapours will be investigated.

Sir Richard Threlfall and the Automatic Microtome

THE appreciative notices of Sir Richard Threlfall which have appeared in NATURE have made no reference to what was probably his first notable invention;—and one that revolutionised an essential method of biological research. As a contemporary of his at Cambridge, among the first who had the opportunity of profiting by his results, I may perhaps be permitted to emphasise its importance. It had been realised for some time that the structure of an animal could be studied with great advantage with the aid of a complete series of sections arranged in order on microscopical slides. Until 1883 no satisfactory method was known of preparing and mounting such a series. Each section had to be separately placed on the slide, where the material in which it had been embedded was dissolved. Parts of the section which were not connected with others floated away and were lost; and the sections already in place were disarranged, involving the necessity of readjusting many of them before the next section could be added. The work involved was extremely laborious, as I can state from personal experience, and the final result left much to be desired. These were, however, the methods with the aid of which F. M. Balfour established his reputation as an embryologist.

The credit of initiating a more satisfactory process is due to W. H. Caldwell, who ascertained that a section of an object embedded in a block of solid paraffin cut so that two of its edges were parallel to one another and to the edge of the knife to be used could be made to remain united on the razor. An important detail in this method was that the block of hard paraffin used for embedding was dipped, before cutting, in a paraffin of lower melting point, which served as the cement uniting consecutive sections. In 1882, Caldwell consulted Threlfall, then an undergraduate at his own College (Caius), leaving it to him to devise a machine which would produce the desired result. This object was duly accomplished; and the microtome, constructed in Prof. Stuart's workshop at Cambridge at Threlfall's expense, was completed in 1883 and proved an unqualified success. Its history has fortunately been recorded in a very recent paper by Threlfall (*Biological Reviews*, Cambridge, vol. 5, p. 357; 1930), who stated that the only biological work he ever did at Cambridge was the preparation, with his microtome, of a complete series of sections of *Amphioxus*, represented (in part) by a ribbon of sections "some yards long".

The original instrument continued in almost daily use in Sedgwick's laboratory at Cambridge for many years after newer patterns had been invented, giving results equal to those of the best of them; and I think I am right in stating that it was still employed when I left Cambridge in 1908. Threlfall had added one essential improvement to Caldwell's original idea. This was the introduction of a method by which the sections were arranged on slides coated with a dilute solution of rubber, by which they became attached to the slide, so that the paraffin could be dissolved without disturbing any of the loose parts. Slides containing sections prepared by the method of Caldwell and Threlfall can be read like the consecutive pages of a book, instead of, as previously, like an incomplete series of detached pages frequently imperfect and out of order. Biological science has to acknowledge a deep debt of gratitude to Threlfall for designing the first automatic microtome.

Melbourn, Cambs,
Sept. 7.

Research Items

Tobacco among Californian Indians.—Knowledge of tobacco and the practice in its use among the Karuk Indians of the Klamath River, California, are recorded, for the most part in their own words, by Mr. J. P. Harrington in *Bull.* 94 of the Bureau of American Ethnology. Literature on this matter among Californian Indians is practically non-existent, and this is the first section of an inquiry among selected tribes in diversified areas of the State. Drake, in recording his visit to what is now presumed to be Drake's Bay, in 1579, mentions "bagges of Tóbah for presents" brought by the Indians. This was *Nicotiana bigelovii* var. *exaltata*, the species now used by the Karuk. The Pomo Indians use *N. glauca*, introduced from South America. Both species now grow wild in this region. Before the restriction of their activities by the whites, the Karuk were typical river Indians, living on rancheros, their food being acorn soup, salmon, deer meat, greens, berries, nuts, and vegetables. Tobacco was cultivated in a simple fashion. In curing, leaf and stems were separated, the latter being pounded to form an inferior kind of tobacco which was used by hunters, priests of ceremony, and doctors as offerings to the Ikxarey, the 'old-time people', who turned into animals, plants, rocks, mountains, and the like, when the Karuk came to the country, and after they had started all customs. The superior tobacco is smoked by men. Women never smoke except when, as doctors, they perform the functions of men. Tobacco is used only for smoking, being chewed only rarely, and never eaten. The pipe is made of wood with a soapstone lining to the bowl, and is sometimes inlaid with abalone. Smoking is practised in the evening only, after the meal. Tobacco-smoke blowing and tobacco tossing accompany all ceremonies and actions in which luck is sought. The thought of the Karuk is so occupied with tobacco, that it enters into the names of places and individuals.

American Prehistoric Basketry.—An attempt to classify the prehistoric basketry of the south-western United States has been made by Gene Weltfish (*Smithsonian Misc. Collec.*, vol. 87, No. 7), notwithstanding the unevenness of the material and the indefinite character of the information relating to some of it. After examination of all the material available from the various sites in the south-western area and its arrangement in accordance with the archæological classification of south-western cultures, it is concluded, in general terms, that certain technical types stand out clearly. In *coiling*, there are three types with triangular foundation elements: basket-maker in two varieties—two-rod-and-bundle-triangular, and two-rod-and-reed-triangular; cliff-dwellers (identical with basket-makers in type, but differing in texture); and a type with three-rod-triangular foundation. One-rod foundation with interlocking stitches occurs with sufficient frequency to be called a type. In sifter coiling there are two types; and in twill plaiting there are two types, the yucca ring baskets being made from the centre of the bottom upwards, and a second form made downwards with the bottom unfinished. The most important implication of the classification is that there appears to be strong evidence of a unified San Juan area in which basket-maker material is concentrated, with more divergent types at the periphery, and one-rod and sifter coiling as perhaps intrusive. The outstanding cliff-dweller types are the close coiled basketry of basket-maker type and the yucca-ring baskets, the latter persisting in modern times at Hopi and Rio Grande Pueblos. The three-rod-triangular foundation is independent of the basket-maker-cliff-dweller complex and may belong to a later horizon. It is identical with the modern coiled basketry of the San Carlos Apaches. The close affiliation of Sikyatki with modern Hopi is supported by basketry evidence. The appearance of a distinct Texas type of coiled basketry south of the Lower Rio Grande probably marks the limit of the prehistoric south-western area.

Helminthes in Man in Rhodesia.—In a helminthological survey of Southern Rhodesia, Dr. W. K. Blackie (No. 5, Memoirs, London School of Hygiene and Tropical Medicine, 1932) records the results of observations made in the Colony in 1930-31. The incidence of helminthic infestations was ascertained by examining both indigenous and immigrant natives and, later, the European sections of the community. Dr. Blackie gives details of the incidence of *Schistosoma hæmatobium* and *S. mansoni* and of the distribution and biology of their respective molluscan intermediate hosts, and records the finding in man (ten cases) of *S. mattheei*, a species described in 1929 from sheep in South Africa, and found by the author in sheep and cattle and in one baboon in Southern Rhodesia. The definitive site of this species in man is the bladder, and the eggs are passed in the urine. Hookworm infestations are present among all sections of the population. The nematode *Ternidens deminutus* was found in about one hundred natives, and an examination of monkeys and baboons along the eastern border of the Colony revealed a high incidence of infection with this worm. The occurrence of *Strongyloides fulleborni* in twenty-four cases appears to be the first record of the natural occurrence of this worm in man. The author concludes that schistosomiasis (especially urinary) is the most important helminthic disease in the Colony and that next in importance are the hookworm infestations.

Improved Anti-Plague Serum.—It was noted in the Report for 1929 of the Haffkine Institute, Bombay, that experimental evidence had been obtained that anti-plague serum prepared by the immunisation of the ox and sheep is more potent curatively than that prepared in the horse. In the Report for 1930 it is stated that an important trial of this new serum on human cases under carefully controlled conditions has been carried out, with encouraging results. Of 43 cases of plague treated with the serum, 15 died, while of 33 similar cases treated on identical lines but without serum, 23 died. In the first series, the recovery of cases with a considerable number of plague bacilli in the blood was noteworthy, and the rapid improvement of others within a few hours of serum treatment was striking.

New West Indian Molluscs.—During an exploration of certain parts of Hispaniola in 1931, Dr. Alexander Wetmore collected a quart bag full of scrapings from under the edges of stones and such-like places on the small island of Beata. The casual collection has proved to be of unusual interest, for in it Paul Bartsch has discovered an amazing number of new land molluscs. The island itself is about 4½ miles long by 4 miles wide, and is formed of much-eroded limestone, densely covered in some places by scrub and cacti. The rubbish collected for shells was obtained along a quarter of a mile bordering the trail going inland from the north shore (*Proc. U.S. Nat. Mus.*, vol. 81, art. 6; 1932). Out of 16 species represented in the collection, the author describes 13 new species, 1 new sub-species, and 1 new sub-genus (*Chrondropomella*). The affinities

of the forms described and figured are distinctly Haitian, but all are so strikingly differentiated that it is safe to believe that Beata Island has for a long time been separated from the larger island. Yet it is only six miles off Beata Point, the southern extremity of Haiti, with which it is connected by a submarine bank at a depth of 12-18 feet below the surface.

Mosaic Disease of the Tomato.—Much confusion about the terms 'streak', 'stripe', and 'mosaic' in relation to tomato diseases must have existed in the minds of market growers. It has been suggested that *Bacillus lathyri* can cause stripe, and that this malady is accentuated by the absence of potash fertiliser in the soil. A short paper by Mr. G. C. Ainsworth in the seventeenth annual report of the Cheshunt Experimental and Research Station, 1931, makes clear the relationship of the three diseases. Mosaic is caused by a virus; streak by a mixture of mosaic and another potato virus. Inoculations from striped plants almost invariably gave mosaic symptoms, and it looks as though the virus has considerable causal connexion with stripe. Progress reports on "Physiological Investigations of Mosaic Disease" are also given in the same publication by Messrs. W. H. Read and B. D. Bolas.

Northern Land.—Some discoveries regarding the little-known Northern Land, or Severnaya Zemlya (formerly Nicholas Land), are given in the *Polar Record* for July. They are the result of the Soviet Union expedition that has been wintering at the observatory on the Serge Kamenev Islands to the west of Northern Land. Extensive sledge journeys prove that Northern Land consists really of three large islands and many small ones. Komsomoletz, the most northern, has an area of 3610 sq. miles and reaches to lat. 81° 16′ N. The narrow Red Army Strait separates it from October Revolution Island (5510 sq. miles), which in its turn is divided from Bolshevik Island (3420 sq. miles) by Schokalski Strait. The expedition worked chiefly on the two northern islands, both of which are mainly lofty and dome-shaped with receding ice-sheets that cover about eighty per cent of the area. These sheets are said to be the remains of a Quaternary sheet which enveloped all the islands and the Taimir Peninsula. Round the edges of the present ice-sheets several nunataks were noticed. Stagnant valley glaciers occur. Northern Land appears to be part of the same post-Permian foldings that are represented in the Taimir Peninsula. Its present outlines are due to a series of Quaternary faults. On the lower western sides there are still faults approximately in a meridional direction. There seems to be a general elevation of the land in progress. The expedition is continuing its work.

Recent Displacements of the Earth's Crust in Japan.—The repeated levellings carried over certain districts in Japan show that crustal movements have been taking place recently, some of them in connexion with great earthquakes, others in regions within which no earthquake has occurred for many years. Prof. C. Tsuboi contributes the fourth of his valuable memoirs on the deformation of the crust with and after the Tango earthquake of 1927 (*Earthq. Res. Inst. Bull.*, vol. 10, pp. 411-431; 1932). In this, he considers the displacements of 226 triangulation points of the third order, in addition to 6 of the first and 41 of the second orders. The complete map closely resembles one already reproduced in NATURE (vol. 126, p. 923), except that it covers a much larger area. Prof. Tsuboi also gives a number of maps representing the displacements in various ways. Of these, one of the most interesting is that showing the principal axes of the strain ellipses. These have very large values of ellipticity along two zones at right angles to one another and coinciding with the Gomura and Yamada faults produced at the time of the earthquake of 1927. The author concludes that the Gomura fault was due to a contracting movement and the Yamada fault to a shearing movement of the earth's crust. Another article communicated by the Institute (pp. 490-491) shows the changes of level along the south coast of the main island of Japan, the route surveyed in 1889–1900 and again in 1931 being 330 miles in length from Okitu to Kusimoto. The principal results are a depression of the west coast of Suruga Bay amounting to 7·5 in., to the west of the bay an elevation reaching 10·8 in. north of the Bay of Atumi, succeeded by depressions of 9·3 and 8·5 in. at the head of the Bay of Ise, which lies a short distance to the south of the central area of the great Mino-Owari earthquake of 1891.

Oil and Gas in Eastern Canada.—Four years have elapsed since the publication of G. S. Hume's account of oil and gas in the west of Canada, and there has just appeared, by the same author, a complementary report on eastern developments (Canada, Department of Mines, Econ. Geol. Series No. 9, 1932). The staying power of these eastern fields has been, and is, remarkable. One has only to refer back to F. G. Clapp's composite memoir on the petroleum and natural gas resources of Canada, published in 1915, to appreciate this. Seventy years ago the first well was drilled on Black Creek, the present site of Oil Springs Field, Lambton County, Ontario, and the discovery of the Petrolia Field followed soon afterwards; to-day, in spite of numerous other 'finds' in this region, these two fields still maintain their supremacy. It is gratifying to note that Ontario still encourages, by successful results, exploration for natural gas, for which product it has a long and enviable record. Stony Creek Field, near Moncton, New Brunswick, is the only oil and gas producing area east of Ontario, and its intensive geological study is being undertaken to provide new light on possibilities in other parts of this province and Nova Scotia.

Relative Abundance of Oxygen and Nitrogen Isotopes.—The discovery of rare isotopes of oxygen and nitrogen from band-spectra has been followed by several investigations of their abundance, with discordant results. In the second July number of the *Physical Review* a careful study of this question is reported by G. M. Murphy and H. C. Urey, on the basis of the absorption spectrum of nitric oxide obtained from a variety of sources. The method consisted essentially in a comparison of the concentrations of the two molecules $N^{15}O^{16}$ and $N^{14}O^{18}$, each of which contains one rare isotope and one common, and leads to a ratio of 350 : 1 for N^{14}/N^{15}. This is in good accord with chemical and mass-spectrograph data, but less than the best results obtained from emission spectra. The apparently erratic contributions of isotopes to the light emitted from a substance still remains an unsolved problem. In the present work, no difference was found in the isotopic composition of the nitrogen and oxygen from the different sources, of varying geological age.

Combustion of Hydrocarbons.—Prof. W. A. Bone's Bakerian Lecture (*Proc. Roy. Soc.*, August) was devoted mainly to a review of experiments on combustion of hydrocarbons, mostly already published, which bear on the nature of the compound formed initially between the hydrocarbon and oxygen. The problem has been to decide if this contains a hydroxyl group, or is some form of peroxide. Prof. Bone inclines strongly to the former view, which is supported by a great weight of qualitative and quantitative evidence,

particularly in the case of the slow combustion of ethane, where 36 per cent of ethyl alcohol has been isolated without a trace of peroxide. In cases where quantities of peroxide, usually small, have apparently been obtained amongst the products of reaction, Prof. Bone considers their identification not conclusive, and the evidence insufficient to prove that they were formed initially and not as further products from intermediate aldehydes. Prof. Bone does not however consider that 'peroxidation' may not occur in rather abnormal circumstances, saying in his summary that "In any case, even if eventually proved valid in particular cases or circumstances, 'peroxidation' can scarcely be regarded as being more than supplementary to 'hydroxylation', nor 'peroxide' as more than a side-product. In other words, it might possibly afford an explanation of 'knock' as an abnormal feature of hydrocarbon-air explosions, but scarcely of the normal course of oxidation therein." In another investigation, reported in the same issue of the *Proceedings*, C. Campbell, W. B. Littler, and C. Whitworth have succeeded in making an estimate of the pressure in explosion waves from the failure under impulsive shearing, induced by the waves, of copper foils the strength of which had been determined statically.

Calcium Equilibrium in Sea Water.—A drift of calcium away from cold polar waters and a concentration of calcium carbonate in the warm shoals of the tropics seems to be a feature of to-day. There is a probable undersaturation of sea water under some conditions and saturation to precipitation point under others. Bacteria are present in the deposits, and something is known of the physiological changes which these organisms can produce in the water. But what changes will produce a precipitate have never been established. The oceanographical aspects of this problem have long been the concern of Wayland Vaughan, who has initiated a full investigation at La Jolla under Haldane Gee, six papers of which are now published in the June *Bulletin of the Scripps Institute* under the title "Calcium Equilibrium in Sea Water". The theoretical considerations are summarised, and it is shown that tropical, shoal sea water should be approximately in equilibrium with solid calcium carbonate. At La Jolla the water may be slightly more than saturated with calcium when its temperature is raised to 27° C. Experimentally it is shown that calcium carbonate can be precipitated from raw sea water by reducing the total carbon dioxide content at a temperature of 28°-30° C., and ammonia tends to reduce its solubility for calcium. As experiments require long periods before approaching a stable state, rigorous conditions could only be established by eliminating all possible biological activity in the water, and this led to Gee's invention of a special apparatus, using Berkefeld filters, which is herein described. This proved successful, and calcium carbonate was precipitated aseptically from sea water under tropical conditions by reducing the total carbon dioxide content of the water. The precipitate was found to consist of needles of aragonite, practically identical in form, size, and optical properties with crystals of natural argonite from the calcareous bottom muds of the Bahamas.

Astronomical Topics

Faye's Comet.—A telegram from the I.A.U. Bureau, Copenhagen, announced the detection of this comet at Bergedorf. B.Z. No. 33 announces that the plate showing it was exposed for $2\frac{1}{2}$ hours by Dr. Wachmann, Dr. Guyot, and Dr. A. Schwassmann. The position on Aug. $30^d\ 0^h\ 37^m\ 12^s$ U.T. was: R.A. (1932·0) $0^h\ 27^m\ 1{\cdot}79^s$, N. Decl. 14° 53′ 32·5″, mag. 12·0. The perihelion passage will be about Dec. 5·68. The ephemeris in the B.A.A. Handbook may be used with the following corrections; Sept. $9 + 1^m\ 20^s + 4'$, Oct. $11 + 1^m\ 36^s + 6'$, Nov. $12 + 1^m\ 27^s + 4'$. As the comet is approaching the earth until Oct. 22, when its distance is 0·71 units, it is likely to brighten considerably. This is the eleventh observed apparition of the comet. It has only been missed at two returns, in 1903 and 1917.

Eleven comets have now been detected in 1932, but one of them (Carrasco) had perihelion in 1931, and two others (van Biesbroeck and Schmitt) were not observed sufficiently to receive permanent numbers.

The Reinmuth Planet, 1932 HA.—The following observations of this body, made by photography at the Union Observatory, Johannesburg, have come to hand; they are the only observations yet available from the southern hemisphere:

	R.A. (1932·0).	S. Decl.
1932 May 7·75017 U.T.	$12^h\ 6^m\ 22{\cdot}88^s$	10° 52′ 20·2″
7·76679	12 6 6·02	10 52 16·8

These, when compared with northern observations, indicate a parallactic displacement of more than 100″; this enables us to obtain a fairly exact estimate of the planet's distance from the earth, and hence of its period. This appears to be longer than the early determinations, and in the neighbourhood of 1·83 years, so that Eros, with its period of 1·76 years, is still the minor planet with the shortest period. If 1·83 years is correct, there will be a recurrence of configurations after 11 years, being 6 revolutions of the planet. There would in this case be a fairly close approach to the earth at the ascending node in the autumn of 1941, and one at the descending node in the spring of 1943. It will be difficult, but perhaps not impossible, to observe it earlier, as its distance from the earth will be considerable.

Forms of Spiral Nebulæ.—The spiral forms of the great nebulæ have engaged the attention of many mathematicians, but hitherto no completely satisfactory explanation has been reached. A recent paper by Mr. B. M. Peek (*Mon. Not. R.A.S.*, May) tries to explain them in terms of some simple assumptions. It is assumed that the nebula is rotating and contracting, so that the angular velocity increases, and at length matter begins to be shed at the rim, when the acceleration balances gravity. It is further assumed that the shedding begins at two opposite points, which are the points where the outward tidal action of external nebulæ is greatest. Once ejection has begun, it is shown that the tidal action of the ejected matter far exceeds external tidal action, and constrains the outer rim to move with the ejected matter.

Different laws for the rate of contraction of the nebula are tried; all give spiral forms for the outer matter, but the best approximation to observed nebulæ is found to be that the contraction varies as the cube of the radius. An extremely good approximation to the form of the nebula Messier 81 is worked out on this assumption. A point which causes Mr. Peek to have some doubt about his results is the shortness of the time-scale. He finds that the times required to reach about three convolutions are of the order of two hundred million years. A few years ago a time-scale of millions of millions of years was generally accepted; but considerations based on the expanding universe have diminished this a thousandfold. Mr. Peek gives one or two hints that may help to span the remainder of the gap. The spirals found by Mr. Peek are not equiangular; in most of them the inner whorls are more circular than the outer ones.

Greenland Hydroids

DR. P. L. KRAMP in two recent papers * discusses the hydroids of Greenland. The area investigated in the first is extensive, comprising the entire west coast of Greenland from Cape Farewell to Etah in the narrowest part of Smith Sound, and several series of stations laid from the Greenland coast across the Davis Strait and Baffin Bay as far west as possible; in several places the investigations being carried through to the coasts of Labrador.

The second paper deals with the hydroid fauna of representative fjords belonging to two groups, the so-called 'Atlantic' and 'Arctic' types. The difference between these two types is that in one the entrance is deep enough to allow the comparatively warm water of Atlantic origin in the deeper parts of the Davis Strait to come into the fjord, in which the bottom water, therefore, has a fairly high temperature. In the other, a threshold at the entrance prevents (or prevents for most of the year) the Atlantic water from entering the fjord, in which the bottom water is therefore very cold. North Strömfjord, investigated by Dr. V. Nordmann in 1911, was selected as the representative of the arctic type; and in the summer of 1912, Dr. K. Stephensen investigated Kvanefjord near Frederikshaab, Bredefjord, north of Julianehaab, and Skovfjord, six miles farther south, as representative of the Atlantic type.

It is an interesting fact that each zoogeographical group of species of hydroids has in all essentials the same bathymetrical distribution in both types of fjord, which agrees with the ascidian fauna as found by Hartmeyer. Stephensen found, however, that the crustaceans, pycnogonids, and echinoderms in North Strömfjord consist entirely of arctic and arctic-boreal species, whereas several boreal and Atlantic forms occur in the southern fjords. The only exception in the hydroids is that the abyssal Atlantic species are wanting in the North Strömfjord; otherwise in both types there are arctic, arctic-boreal, boreal, and cosmopolitan species in almost the same proportions at similar depths.

Species of all the zoogeographical groups, even boreal forms, were found at considerable depths and at low temperatures in North Strömfjord, but Dr. Kramp is of the opinion that the late summer and autumn temperatures in deep water rise to fairly high values. Stephensen and Hartmeyer emphasise the constantly negative temperature of the water at all depths from about 60 m. downwards, but Dr. Kramp observes that some hydroids are able to live for a long time under very unfavourable conditions of temperature if there is a short period when conditions are favourable. If the temperature rose sometimes to one or two degrees above zero, the presence of these boreal species would be quite explicable. On July 31, 1911, the bottom temperature at one of the stations near the entrance to the fjord at a depth of 170-200 m. was 1°-2°, and later in the year, according to Dr. Kramp, it will probably be higher, and this comparatively warm water will enter the fjord and mix with the other water layers, causing a rise in temperature for a time. As he suggests, the positive temperatures sometimes noted from these depths in Dr. Nordmann's journal, and considered erroneous, may not be altogether wrong, and there is no doubt that the violent currents cause a fair amount of mixing of the water layers. Thus the author explains the presence of some boreal species of both hydroids and ascidians which are able to propagate and grow at intermediate depths in North Strömfjord as due to the combined action of the influx of Atlantic water from the outside and of the vertical movements which bring down the surface water, heated during the summer, resulting in an increase of temperature in the deeper strata at certain periods of the year.

Dr. Kramp has also recently published "A Revision of the Medusæ belonging to the Family *Mitrocomidæ*". † As medusæ are of considerable use as indicators of sea-currents, it is important to be certain of the species with which we are dealing, and the memoir is very helpful in enabling us to distinguish the members of this family, at the first glance so similar to one another.

Megalithic Monuments of Brittany

IT was to be expected that megalithic monuments, and in particular circles, stone or other, would occupy much of the attention of the International Congress of Prehistoric and Protohistoric Sciences, recently held in London, especially as arrangements had been made to give many of the overseas members their first opportunity to view the site of the wooden circles at Woodhenge and 'The Sanctuary'. In fact, two whole sessions of Section III.A of the Congress were devoted to the subject. Among the communications then presented, special interest is attached to that of the veteran field archæologist, M. Z. Le Rouzic, whose prolonged and practical acquaintance with the problem of the megalith in Brittany gives him unquestioned authority on the subject chosen for his communication: "Morphologie et chronologie des monuments sépulchraux de Morbihan".

M. Le Rouzic classifies the megalithic monuments into ten groups as follows:

(1) Dolmens with rather irregular chambers and corbelling and an entrance passage roofed with small blocks; the whole is buried in a tumulus with a limiting circle of upright stones. Associated are polished axes, some small and votive, fine flint arrow-heads with barbs and stem, flint scrapers, borers, etc. The pottery is both fine and coarse; with these are pot spindle whorls and stone beads. An example is Parc Guren (Crac'h).

(2) Dolmens with long entrance passage and side chambers, built of large blocks. Also '*allées couvertes*' with port-holed supports. Corbelling is usually above large block-uprights. The monument is embedded in a cairn and often surmounted by a menhir. Uprights are often engraved. Associated are bell-beakers, 'bowls-with-support', beads of callais, etc., ornaments of hammered gold, as well as objects of Group 1. There are a few foreign types of fine flint work and copper or bronze daggers. Both burials and cremations are found—Kercado, Mané Lud, are good examples; also some '*allées couvertes*' of elbowed form (Le Pocher, Plougoumelen). Kerlescant '*allée couverte*' formerly had a port-hole. Île Longue is the finest corbelled tomb in Brittany.

(3) Tumulus with quadrangular cist, or cists of blocks or dry walling with hearths inside them. Purely neolithic associations. The second tumulus of

Le Manio contains 39 cists. There is a decorated menhir above it.

(4) Dolmens in a tumulus with contemporary cists. This is probably a combination of Nos. 1 or 2 with No. 3. No. 2 is probably an intrusive culture, No. 1 an impoverished local form of No. 2, and No. 3 either another local form based on No. 2 or an intrusive type of some other origin.

(5) Monuments containing a closed dolmenic chamber, often built with dry walling. (*a*) Yield fine jadeite, etc., axes, some very small and provided with suspension holes, ring-discs, many callais beads, but very little pottery; for example, Mt. St. Michel (Carnac) and Ker Lud. (*b*) Yield no callais but have arrowheads of translucent flint, copper or bronze daggers, halberds, and flat axes. The chamber is somewhat sunk; originally it had wood-covered walls. None of these monuments are found in the sacred Carnac region. They are probably the work of invaders or strangers. Examples are Mané-er-Loh, Mané Roullarde, Mané Kervilor.

(6) Tumulus enclosing a closed dolmenic chamber and stone cists (compare No. 4, but in this case a hybrid of 3 and 5), handled pots. The dating is early bronze age; examples are St. Germain, Erdeven.

(7) Tumulus with rectangular dry-walled cists. Associated are lances and blades of bronze. These are probably the poor successors of 5*b* and 3 crossed. Mané Rumentier is an example.

(8) Tumulus with six-slabbed cists. With these are bronze pins and black pottery. The dating is iron age; example, Mané Bekernoz.

(9) Tumulus with rectangular fossa in a circular enclosure with four-handled pots, objects in bronze and iron, and beads of blue glass. No. 7 at Le Rocher (Plougoumelen), Hallstatt and La Tène periods.

(10) True La Tène burials in subterranean chambers are found only in La Tène III.; for example, Kerfraral. To the same period belong tumuli with small entrance passages. They are often filled with black earth and charcoal and contain a hearth. Examples are Mané Roullarde, Mané Bras de Kervilor. No. 10 indicates the persistence of the influence of Nos. 1 and 2.

A second communication dealing with megalithic monuments in Brittany was presented by Prof. C. Daryll Forde on "The Typology of Megalithic Monuments in Brittany". Prof. Forde pointed out that Brittany contains a very complete range of megalithic and associated tombs from corbelled and rock-hewn chambers to small cists and coffers. The passage chamber is the basic form, and it is probably both relatively and absolutely most abundant in south Morbihan. It is usually truly megalithic. The Breton tombs show close parallels with the southern Iberian. The development of a multiple passage tomb in south Morbihan may have been the starting point for the rough grouped chambers found outside that region, and may have been the model for some of the tombs in the English long barrows.

Angled galleries and large closed chambers are specific Breton types, rare outside the peninsula, and mostly confined to the south. The covered gallery ('*allée couverte*'), in form, distribution, and some characteristic grave-goods, indicates connexions with north-east France; but its contemporaneity with other tombs is shown by the presence of the bell-beaker. A number of auxiliary grave types are associated with the larger tombs: small coffers of heaped stone fragments, stone cists, and trench graves. These are sometimes found under the same tumuli as megaliths without suggesting secondary interment.

The material from tombs of different type does not show much variation. While certain objects have a restricted geographical range, they are not confined to a single type of tomb. The concentration, fine construction, and abundance of Iberian parallels in southern Morbihan indicate that this was the first centre of megalithic construction in Brittany. The culture stagnated after the first diffusion, while the Armorican graves of the late bronze age show a very complete break with the tradition of the megalith builders.

British Phenology

THE Phenological Report, 1931, issued as a special number of vol. 58 of the *Quarterly Journal of the Royal Meteorological Society*, is the forty-first report of this kind. It deals primarily with variations in different parts of the country in the dates of the first appearance of certain birds and insects, of the first singing of various species of bird, and of the date of commencement of flowering under natural conditions of various plants of the country-side; it is consequently mainly in the form of statistical tables. Observers increased from 500 in 1930 to just over 600 for this issue, mainly as a result of broadcasting; while the south is well supplied with observers, there is still opportunity for more in the more remote areas, especially Wales, Scotland, and Ireland.

This particular number does not differ much in form from those for other recent years, although it contains a new feature in the form of a map showing what are described as average spring migrant isophenes—a system of lines of equal average date of arrival of twenty species of migratory bird based on records obtained during the seventeen years 1914–30. The dates are in the notation generally adopted in phenological work, that is, they are expressed as the serial number of the day in question, Jan. 1 being taken as 1, Feb. 1 as 32, and so on. Such a map of normal dates of arrival can be used when it is desired to know to what extent a particular year is abnormal in regard to the average time of arrival of migrants, and also may give information about the nature of bird migration to anyone capable of interpreting the figures; for example, the existence of closed areas of relatively late arrival superimposed upon a general retardation from south to north (the latter exceeding a fortnight as between southern England and northern Scotland), often corresponding roughly with elevation of the land, suggests a secondary feature of the migrational movement connected no doubt with the well-known backwardness of plant and insect development in higher and therefore colder localities, complicated by other factors if the lines are to be trusted.

A weather summary based on the published records of the Meteorological Office is included to enable the student to trace the effects of the weather upon the phenological records, and a table which appears for the first time in the present Report is Table I.D, showing the number of *weeks* with 'decided' and 'excessive' divergences of the three main weather elements, based on unpublished weekly weather returns. Table VI. includes *decade* means of the thirteen plants used in the records for comparison. The unique series of observations of trees and shrubs taken at St. Michael's, Tenbury, Worcestershire, in Table VII., and those of plants and birds taken at Hevingham, Norfolk, in Table XIV., are making their last appearance owing to death and infirmity.

The year 1931 was particularly interesting on account of the severe frosts in March and October, and much dull weather in the late summer.

Scientific Aid in Agriculture

THE story of the founding at Indore, in Central India, of an Institute of Plant Industry, its unique territorial associations and duties, the work in hand, and its bold, comprehensive policy of research has become widely known through the writings of its first director, Mr. Albert Howard. These have now been extended by articles in the *Empire Cotton Growing Review*, vol. 9, Nos. 2 and 3, 1932, entitled "The Improvement of Cotton Production". Plans are explained for dealing with specific cotton problems in Central India, but the articles also contain an important treatment of the general question of policy in agricultural research. During the past twelve months enforced economies have made responsible bodies all over the world scrutinise closely their disbursements on agricultural research. Some have inclined to grasp an excuse for ending scientific work with which they never sympathised, but the more common and the reasonable reaction has been to ask whether all the work in progress is well conceived and likely to benefit industry. Howard, speaking of the present position—a superabundance of raw cotton and low prices—asks if science can help the cotton industry under such conditions, and he bluntly adds that if it cannot "the days of agricultural research are indeed numbered".

Against agricultural research in general is laid the charge that practical problems have always been approached by one science at a time, working alone. This has imposed on research stations an inelastic organisation which, weakly following the strict departmentalism required for the teaching of the sciences, has produced rigid specialists and set them to attack isolated fragments, leaving major problems untouched. It is suggested that research must concern itself less with the details of existing agricultural methods and more with the possibility of evolving wholly new methods to meet the changes of situation which have swept over all branches of crop production. If cotton growing is to be substantially aided, the living plant must be the centre of action, and this can only be studied effectively in relation to the soil, the agricultural conditions, and the economic uses. Study of this kind, however, is not provided for by the accepted subdivisions of agricultural science. A new, broader outlook on agricultural problems is needed, with consequential changes in research organisation.

When he deals with "the improvements which really matter", Howard prescribes for cotton-growing improvement "a well-balanced combination of agronomy and genetics with soil science". Against insects and fungi the cultivation of suitable varieties in an efficient manner is urged as the only practicable method, and support is derived for this view from the history of the now famous sugar researches in Java.

Some of the minor points may be considered contentious and open to criticism, but the main thesis is an important statement on a great and urgent problem. To ask for attack on a wide front, for joint action by the various formal divisions of science, and that the structure of the industry itself should be added to the subjects for investigation, is to ask for no more than systematic planning of research, based upon careful reconnaissance of industry. Whether crop production can better be helped by inviting specialised branches of science to choose their own problems or by trying to resolve great practical problems into their scientific components and applying the sciences to these is the essential question these articles try to answer.

F. L. E.

Annual Exhibition of the Royal Photographic Society

THE seventy-seventh annual exhibition of the Royal Photographic Society was opened on Sept. 9 at the Society's house at 35 Russell Square, London, W.C. The exhibition will remain open each weekday until Oct. 8.

The Scientific and Technical Section this year, besides its usual features, possesses a notable series of photographs of the invisible. On one hand are some excellent examples of fluorescence photography of visually undecipherable documents. Here the invisible writing is shown by differential fluorescence of the parchment or paper surface when exposed to ultra-violet radiation. At the other end of the scale, photography by means of plates sensitive to the infra-red is shown in several aspects. First are many examples of long-distance photography through haze. Next are shown photographs taken in complete darkness, among them being photographs of hot flat-irons taken by their own invisible radiation. A very interesting example of the application of infra-red photography has been made in the examination of some rare old books in which certain passages were deleted some three hundred years ago by the censor for the Spanish Inquisition. The ink used for the deletions is, however, transparent to infra-red radiation, though the original printed characters are opaque; infra-red photography has thus been able to make tne original paragraphs easily legible. Infra-red photomicrography has been mentioned recently in these columns; some fine examples of this work are shown in the exhibition. Lastly, spectrograms are shown taken with plates sensitised with xenocyanine; by using this sensitiser many new lines have been recorded in the spectra of the rare gases between 8500 and 11,000 A.

Chemical engineers will be interested to find on view a working model of an electrolytic plant for the recovery of silver from used fixing baths. The exhibit represents part of a motion picture film laboratory in which millions of feet of film annually are developed, fixed, washed, and dried. In one of these factories the cost of the hypo fixing baths may easily exceed £2000 a year, and the unreduced silver bromide which is dissolved from the film may represent as much as £7000 worth of metallic silver, even at its present low price. Previously, the silver was salvaged by throwing it down as a sludge of silver sulphide, which had then to be treated by a somewhat costly refining process. The silver is obtained by the new process as 98 per cent pure metal on stainless steel cathodes. Fortunately, owing to an admixture of a small amount of gelatin, the deposit is very brittle, so that it can be readily scaled off from the cathodes. The hypo itself is regenerated by the electrolysis, and is run back into the fixing tanks for further service; owing to dilution and to the accumulation of soluble bromide, however, the solution would eventually become unfit for use; for this reason, about one-third of the desilvered solution is run to waste, and fresh hypo is added to the fixing baths. The total consumption of hypo is thus reduced to about one-third of the amount employed formerly.

In its other sections the exhibition maintains its customary high standard. The Colour Section, while not being large, contains some very fine examples of three-colour portraits. The examples of Press photography bear ample witness to the very high sensitivity obtained in certain new panchromatic materials.

University and Educational Intelligence

CAMBRIDGE.—Dr. Walter Langdon Brown has been appointed regius professor of physic in succession to Sir Humphry Rolleston, who retires on Sept. 30 on completion of his term of office.

Mr. J. O. Giršavičius, of Gonville and Caius College, has been elected to the Benn W. Levy research studentship in biochemistry.

LEEDS.—A series of sessional courses for teachers has been arranged to be held on Saturday mornings. The biology course will be divided into classes on the biology of the tree by Prof. J. H. Priestley and on the fundamental biology of animals by Mrs. A. Redman King. Mr. J. C. Gregory will give a course of lectures on elementary science, and Mr. W. P. Welpton on the teaching of mathematics. Although these courses are intended for teachers, particularly those in Senior Schools, other students may enter. Further information can be obtained from the Registrar.

A COURSE of lectures on television has been arranged to be given by Mr. J. J. Denton, secretary of the Television Society, in the Electrical Engineering Department of the Borough Polytechnic, Borough Road, London, S.E.1. The lectures will be given on Thursdays, commencing on Oct. 6. Further information can be obtained from the Principal.

A VACANCY exists for an assistant master at the Prince of Wales' Royal Indian Military College, Dehra Dun, United Provinces, India. The College was established in 1921 for the education of Indian boys in preparation for entry into Sandhurst and other military colleges and eventually for a military career as officers. The number of pupils at present in the College is 115. The normal age of entry is 11-13 years, and the course extends over six years. The assistant master appointed will be expected to teach science, especially physics. The starting salary varies from 550 to about 800 rupees a month according to age, and rises to 1500 rupees plus £30 a month (1 rupee = 1*s*. 9*d*.). These rates are, however, being subjected to a temporary reduction, not exceeding ten per cent, owing to the present state of financial stringency. Free quarters are provided, and the master appointed will receive an outfit allowance of £50 and free first-class passage to India. One of the assistant masters at the College is at present on leave in Great Britain and would be pleased to meet any intending candidates. Further information can be obtained from the Secretary, Military Department, India Office, London, S.W.1.

A "HISTORY of the Municipal University in the United States" has been published as a bulletin (No. 2 of 1932) of the Office of Education, Washington. The author, who is professor of the history of education in the Ohio State University, describes the origin and development of all those universities, eleven in number, which are directly under the control of municipal authorities. Universities which are municipal in this complete sense appear to be peculiar to the United States, where they represent an attempt to do for the citizens of the city what the State university does for the citizens of the State. Their emergence is regarded by the author as part and parcel of a great movement of increasing participation of public authorities in the provision and control of modern education, and as being an extension upward of the public school system of the city. Many of the newer universities in England and Germany, although not directly under the control of municipalities, are, like the American municipal universities, closely linked with them by mutual services, and owe their origin partly to a desire to provide educational opportunities for persons who would be unable to seek them elsewhere. In these and other institutions for advanced instruction and research where the work is closely related to local needs this historical survey will be read with interest.

Calendar of Geographical Exploration

Sept. 20, 1519.—First Circumnavigation of the Globe

Ferdinand Magellan sailed from San Lucar with a fleet of five ships under instructions to sail south by the coast of Brazil and thence to penetrate to the Moluccas. During their five months' stay at Port St. Julian, lat. 49° 20′ S., the Spaniards came into contact with Patagonian tribes and were struck by their tall stature. Sailing south, Cape Virgins was reached and the great discovery made; the passage through the strait was difficult and occupied 38 days, one ship deserting during the exploration. The trade winds carried the three vessels which passed the strait far from the Pacific islands, and in their nearly four months on the open sea the men suffered from hunger, thirst, and disease; nineteen died. Puka Puka in the Paumotu Archipelago was sighted on Jan. 24, 1521. Magellan was killed by natives on the island of Mactan on April 27, 1521. He had proved that the world was round, and had opened the way for the circumnavigation of the globe which was completed by Sebastian del Cano in the *Vittoria*, which reached San Lucar on Sept. 6, 1522, the only vessel of the five to return. Magellan left no record of his journey, and it was long before his remarkable feat of seamanship and endurance was recognised as one of the greatest events of exploration. He achieved the linking of western Europe with eastern Asia as a result of deliberate planning and first-class seamanship. By origin he was a Portuguese nobleman and his first voyages were undertaken for Portugal, but when he fell into disfavour with King Manuel he adopted Spanish nationality, and it was in the service of Charles V. of Spain that he made the voyage on which his fame rests.

Sept. 20, 1893.—Drift of the *Fram*

The *Fram* was frozen into the ice off the New Siberian Islands in 77° 30′ N., and drifted with the ice, on the whole in a north-westerly direction, reaching 85° 55′ N. in 66° 31′ E., the highest latitude ever reached by a ship. Nansen had convinced himself that there was a polar drift, and having planned the *Fram* to resist crushing in such a way that, if nipped in the ice, the opposing masses would pass under her and lift her to the surface, he deliberately committed her to the ice and awaited the results. The originality of the plan was only equalled by its daring: the party numbered 13 in all. After the second winter on the ice, when the northward movement seemed to be checked, Nansen and Lieut. H. Johansen left the ship in order to explore the regions towards the pole by travelling on ski, with dog sledges carrying kayaks. They could not hope to reach the drifting *Fram* again, but trusted to reaching Spitsbergen and there finding a tourist steamer. The intrepid explorer met with the success his plan deserved. Nansen and Johansen reached 86° 5′ N., the nearest to the pole that had ever then been attained. They travelled south with much difficulty, encountering many dangers, including attacks by wild beasts. They wintered on Jackson Island in a stone hut which they built and roofed with their silk tent. They lived like the Eskimo on bear and walrus meat, cooked over a blubber lamp. Travelling

south in 1896, they met F. G. Jackson, in whose relief ship they returned to Norway, arriving at Vardö on Aug. 13, 1896, full of anxiety as to the fate of the *Fram*. On that very day the *Fram* broke out of the ice, the whole party meeting in Tromsö the following week. On this unique and daring journey no life was lost, the ship was undamaged, and a rich harvest of scientific data was secured.

Sept. 22, 1631.—Foxe Channel

Luke Foxe reached his highest latitude, 66° 47′, after following the coast of Foxe Land and passing through Foxe Channel. He had left England in May 1631 in search of the north-west passage, feeling confident that he would return with a cargo of pepper from the East Indies. He did not succeed in this, but he rendered great service to geography by completing a rough survey of Hudson Bay, and by discovering and penetrating far into Foxe Channel. He also drew a map, now famous, showing with considerable accuracy the arctic regions as then known.

Societies and Academies

LONDON

Institute of Metals (Annual Autumn Meeting), Sept. 12–13.—**H. J. Gough**: Corrosion fatigue of metals (Autumn Lecture). Corrosion fatigue of metals is defined as the behaviour of metals subjected to cyclical stresses while exposed to an environment of an oxidising nature. Following a brief historical account, the nature of the general problem, the nomenclature employed, and the characteristics of laboratory tests are stated; representative failures in service are described. Consideration is then given to the general influences of chemical composition, heat treatment, and cold working on the resistance of metals to corrosion fatigue, also of the effect of time, number of cycles, and corrosivity of environment as factors in the process. Primary importance is attached to the behaviour of protective films under the straining actions associated with cyclical stressing. —**W. R. Barclay, G. A. V. Russell, and H. Williamson**: Modern works plant and equipment for the hot-working of nickel and nickel alloys. This paper describes a modern plant erected in Great Britain as a result of experience in the hot-working of nickel and its alloys, and a close study of the conditions under which similar work is carried out on the Continent and in America. The main features of the plant are: (1) hydraulic forging press; (2) hot rolling mill. The heating of sheet-bar for rolling into sheets is carried out in a specially designed electric resistance furnace.—**G. L. Bailey**: Mould materials for non-ferrous strip ingot casting. Grey cast iron is the material most generally used for moulds for the casting of non-ferrous strip ingots. Cast-iron moulds are subject to two particular defects, gas evolution from the face of the mould when this is overheated during pouring ('blowing'), and transverse cracking of the working faces. Copper is considered the most satisfactory material for strip ingot moulds. Its high thermal conductivity prevents serious temperature gradients and consequent distortion.—**E. J. Daniels**: Some reactions occurring in 'hot-dipping' processes. The part played by fluxes has been investigated and a general agreement found with diverse processes. The contamination of the liquid metal is an inevitable factor in hot-dipping, soldering, etc., and methods for controlling it are indicated.—**N. P. Allen**: The effect of pressure on the liberation of gases from metals, with special reference to silver and oxygen. The liberation of oxygen from silver during solidification has been studied by means of cooling curves. The gas is evolved when the 'internal pressure' of the dissolved gas becomes greater than the hydrostatic pressure of the liquid metal, and by applying a sufficiently large pressure to the liquid metal the formation of blowholes can be prevented. The equilibrium of the silver-oxygen system is discussed and the existence of a eutectic shown.—**J. D. Grogan and T. H. Schofield**: On the removal of gases from aluminium alloys by mixtures of nitrogen and volatile chlorides. Raw cylinder nitrogen may be employed. The quantity of chloride needed is small. Metal treated in this way possesses excellent mechanical properties.—**H. A. Sloman**: Researches on beryllium. With the progressive elimination of metallic impurities, the brittle nature of the early metal was not greatly altered. This brittleness was afterwards found to be due to a beryllium/beryllium oxide eutectic surrounding the metal grains. Most of the work has been directed towards the elimination of this oxide. Of all the methods attempted and described here, sublimation *in vacuo* has been the most effective.—**R. J. M. Payne and J. L. Haughton**: Some attempts at making beryllium-magnesium alloys. A description is given of various methods which were tried for the production of beryllium-magnesium alloys, all of which were unsuccessful.—**D. Stockdale**: The constitution of the lead-tin alloys. The micrographic method, two thermal methods, and a modified electrical conductivity method have been used in the determination of the solubility of tin in lead, which is shown to be 19·5 per cent by weight, at the temperature of the eutectic. This value is considerably higher than any other previously obtained.—**M. Cook and H. J. Miller**: The effect of different elements on the annealing and grain-growth characteristics of alpha brass. An examination has been made of the effect of additions of iron, phosphorus, manganese, and aluminium separately, and of aluminium with nickel, and aluminium with silicon, on the annealing characteristics of alpha brass by determining diamond pyramid hardness values and making grain-size measurements on cold-rolled alloys annealed at various temperatures, while the tensile properties on a number of alloys representative of the various series investigated have also been studied.—**J. H. Watson**: Liquation or 'inverse segregation' in the silver-copper alloys. The first formed primaries, whether of silver or of copper, are free to move under the influence of gravity, when the alloy is maintained for sufficient time at temperatures between the liquidus and the solidus. The primaries which have segregated under the influence of gravity are repelled from their position by the application of severe local chilling to their vicinity.

(*To be continued.*)

PARIS

Academy of Sciences, Aug. 1 (vol. 195, pp. 345-404). —**J. Costantin**: High-altitude heredity acquired by the sugar cane. Historical account of the relations between the resistance of sugar canes to disease and the altitude at which they are grown, and the results of transplanting from high to lower altitudes.—**Paul Janet**: The International Congress of Electricity of 1932.—**P. Pascal and Mlle. J. Hansot**: The quantitative study of the adsorption of metallic cations by cellulose. Results with lead nitrate, thallium nitrate, and lead chloride are given graphically.—**Lucien Daniel**: A curious graft of the chestnut and pear trees. An account of a pear tree on which a chestnut has been accidentally grafted. Each bears its proper fruit and

foliage, and both are fed by a single trunk.—**E. Bataillon and Tchou Su**: The comparative study of the initial kinetic process in the impregnated egg of *Hyla* at various stages of growth.—**Vladimir Bernstein**: The directions of Julia and of Borel of integral functions of finite order.—**A. Lafay**: The prediction of the action of a rapidly changing wind. Application to the Katzmayr effect and to autorotation.—**R. de Fleury, H. Portier, and S. Benmakrouha**: Rules of transpositions with homogeneous factors of safety of equilibrium and stability at critical deformations.—**G. Rougier**: The variations of atmospheric absorption.—**J. Cayrel**: The permeability of a vacuum and the theorems of Chipart.—**Armand Bogros and Félix Esclangon**: The excitation of atomic jets by an electromagnetic discharge of high frequency. The method described promises to be of service in the study of the hyperfine structure of spectral lines.—**G. Bruhat and P. Chatelain**: The realisation of a photoelectric polarimeter.—**P. Soleillet**: The fluorescence of a jet of zinc atoms.—**F. C. Chalklin and L. P. Chalklin**: The partial absorption in the region of the soft X-rays.—**Mlle. J. Pernet**: The magnetic rotatory power of cerous chloride in aqueous solution. The thermal variation.—**P. Fourmarier**: The response of a gas-filled photoelectric cell to a sudden illumination. Study of the causes of lag in photoelectric cells: the results are given in three curves.—**Lemarchands and Jacob**: Remarks on chemical inertia. Starting with the hypothesis that the reaction temperature between a metal and chlorine should be proportional to the product of the boiling points of the metal and the chloride formed, experimental results are given for the reaction temperatures of a number of metals with chlorine. The concordance between the measurements and the calculated temperatures is satisfactory.—**Desmaroux and Mathieu**: The influence of temperature on the structure of nitrocellulose films. A discussion of the causes of the differences between the authors' results and those of J. J. Trillat. The concentration of the solutions and the temperatures at which the film is dried affect the crystalline form.—**Berthon**: Selective adsorption by silica gel in ammoniacal solutions of the heavy metals. In ammoniacal copper solutions the complex ion $(Cu(NH_3)_2)$ is adsorbed. Ammoniacal zinc sulphate solutions behave similarly.—**Georges Delbart and Edgar Lecœuvre**: Contribution to the study of low carbon cast-irons.—**Rambaud**: A particular case of allyl isomerism.—**A. Mailhe and M. Renaudie**: The formation of various organic sulphur compounds starting with ethylene hydrocarbons. The hydrocarbons (ethylene, propylene, butylene, and amylene) mixed with hydrogen sulphide were passed over silica gel at 700° C. A complex liquid mixture was obtained containing alkyl sulphides, thiophene and its homologues, and other sulphur compounds.—**Romer**: The present condition of Mt. Pelée. The eruption of 1929-1932 resembled that of 1902 but was on a smaller scale. Some of the protective topographical features have disappeared: an eruption on the south or south-east side of the new cone might be very dangerous.—**Y. Khouvine**: Study by means of X-rays of the chitin of *Aspergillus niger*, *Psalliota campestris*, and *Armillaria mellea*. Chitin of vegetable origin has not only the analytical characters of animal chitin, for example, the crayfish, but also has the same crystalline structure.—**Maurice Leriche**: The first fossils discovered, at the north of Angola, in the prolongation of the Lubilash strata, and the synchronism of the Lubilash and Lualaba deposits.—**A. and R. Sartory, J. Meyer, and E. Keller**: The determination of the quantity of magnesium contained in the essential foods and water of different communes of Alsace and Lorraine and its influence on cancer mortality.

Cape Town

Royal Society of South Africa, April 20.—**S. M. Naudé**: The spectroscopic determination of isotopes. Molecular spectra offer a much greater opportunity for the discovery of isotopes, since the mass of the constituent atoms of the molecule enters directly in the expressions for the vibrational and rotational energy of the molecule.—**B. F. J. Schonland and J. P. T. Viljoen**: A penetrating radiation from thunder-clouds (see Nature, Sept. 10, p. 399).—**M. Rindl and P. W. G. Groenwoud**: A contribution to the chemistry of *Rauwolfia Natalensis*. The bark of the so-called 'quinine tree' (Koorsboom) is credited with possessing medicinal virtues. The cold alcoholic percolate furnishes: (*a*) Cane sugar. (*b*) An amorphous yellow alkaloid which, when administered orally or subcutaneously to cats in doses of 27 mgm. per kg. body weight, causes an elevation of temperature. The alkaloid has no definite melting point, and it resisted all attempts to obtain it or one of its derivatives in crystalline form. It is obtained by fractional precipitation of the aqueous alkaloid solution with sodium carbonate. (*c*) An amorphous alkaloid extracted from the aqueous alkaline solution with ether and giving the Rauwolfine reaction with concentrated nitric acid. (*d*) An amorphous alkaloid extracted from the aqueous alkaline solution with ethyl acetate and giving a fluorescent solution. This alkaloid does not give Rauwolfine reaction. (*e*) One or more alkaloids which appear to be very soluble in water and are not removed from the aqueous alkaline solution by shaking with immiscible solvents.

Rome

Royal National Academy of the Lincei, March 20.—**T. Levi-Civita**: Theorems of unicity and of existence for the small oscillations of a vortical thread of nearly circular form.—**L. Tonelli**: A theorem of the calculus of variations.—**S. Cherubino**: A property of oblique intuitive curves.—**J. Mirguet**: Certain new direct infinitesimal notions.—**G. Lampariello**: The instability of helicoidal vortices.—**G. D. Mattioli**: The reduction of degree of the canonical systems by means of generic integrals.—**N. Moisseiev**: The law of resistance to the motion of bodies in a pulverulent medium. (3) General case of an incoherent agitation.—**G. Supino**: Deformation of strips.—**G. Conti**: Contribution to the study of the variation of latitude.—**T. Alippi**: Certain peculiarities of the annual variation of the relative humidity. In relation to the recent communication on this subject by Viola, the author quotes the following conclusions drawn from various memoirs by Eredia (1908, 1919, 1931), dealing with observations made at a number of Italian towns. In coastal towns the moisture is lower in winter and higher in summer than in the interior of the country. On the seaboard the variations in the relative humidity, although marked, are less than in the interior. At Genoa and on the western Riviera generally, moisture is scanty (sometimes below 50) in January and reaches its maximum in summer and autumn; this anomaly is attributed by Eredia to the influence of air-currents.—**Maria Lombardini**: Calculation of the circuitation in the movements of the atmosphere.—**P. Straneo**: A new unitary theory of gravitation and electricity by absolute geometrisation. The author's studies on the unitary problem of macroscopic physics lead to a solution which, owing to its maximum generality and its extreme simplicity, appears to be definitive.—**G. Devoto**: Investigations on the dielectric constant of liquids. (7) Dielectric constant and electric moment in aqueous solution. With the α-amino aliphatic acids, distinct proportionality exists between the dielectric constant and the electric moment; this is

confirmed by the results recently obtained for glycylglycine.—C. Jucci and C. Manunta: The colouring matter of the silkworm cocoons of the Japanese green race. This pigment, for which the name bombiclorin is proposed, dissolves very readily in water and only sparingly in alcohol, and forms yellow salts with alkalis.—M. Anelli: Folding of Pleiocene soils in the Reggian Appennines.—R. Pampanini: Plants collected in Libya by the Desio mission (1931).

Forthcoming Events

Societies

THURSDAY, SEPT. 22

OPTICAL SOCIETY.—Special General Meeting at the Imperial College of Science and Technology, at 5.30 P.M.

Congresses

SEPT. 19–24

BRITISH MYCOLOGICAL SOCIETY.—Annual General Meeting at the Haslemere Educational Museum, Surrey.

Wednesday, Sept. 21.—Miss G. Lister: "Field Notes on Mycetozoa" (Presidential Address).

SEPT. 21–23

FARADAY SOCIETY.—Second Colloid Meeting at Manchester. Discussion on the "Colloidal Aspects of Textile Materials and Related Topics".

SEPT. 23–26

ASSOCIATION OF SPECIAL LIBRARIES AND INFORMATION BUREAUX.—Ninth Annual Conference at Somerville College, Oxford.

Friday, Sept. 23.—Sir Charles Sherrington (Presidential Address).

Prof. J. L. Myers: "The Relationship between Science and the Humanities".

Saturday, Sept. 24.—Dr. S. C. Bradford and Prof. A. F. C. Pollard: "Classified Subject Indexes to Periodical Volumes".

Prof. M. Greenwood: "History and Sources of Official Vital Statistics".

Chemical Societies and Co-operation

THE industrial complexion of the present-day world, with its political and financial complications, has of necessity led numerous institutions concerned with the production and distribution of commodities, and with means to assess and exchange their value, to abandon convenient and traditional procedure and to discover alternatives which have the merit, under the new conditions, of combining self-preservation with the supply of the public needs. The science of chemistry has been harnessed to the industrial machine with a rapidity which appeared unlikely twenty years ago, and its record of service is already such as to presage the extension, as quickly as the difficulties of the moment permit, of this collaboration.

Responsibility for promoting such co-operation is shared by the Government and other public bodies, by industrialists, and by the chemical profession itself; but whilst the acquisition of chemical knowledge is a task shared directly or indirectly by all of these, its distribution is a burden which is borne almost entirely by the producers themselves. Hence many institutions devoted to the extension of scientific knowledge are faced with the same problems as the interests to the assistance of which they have been summoned. They have now to consider afresh how they can best realise their increasing responsibilities towards the national needs, while at the same time finding means to guard against serious deterioration of their distributing organisation.

Chemical societies, in common with other scientific bodies, are not greatly—if at all—concerned with questions of professional rewards, for the care of which provision is made by appropriate professional organisations. They acknowledge that it is one of their duties to promote scientific intercourse among their members, and to make such provision as may be deemed necessary to facilitate research and its discussion; but the principal duty which is laid upon them by common consent as well as by the force of circumstances is to publish to the world the records of original investigation, to do so as far as is possible without any restriction other than the scientific value of the material, and to prepare and distribute summaries of current researches in a world-wide or limited field.

This twofold publication is the very foundation of all new knowledge, and the disastrous effect of any appreciable curtailment—apart from such devices for abbreviation as may be easily intelligible to workers in the science—is only too fully realised. Consequently, much serious consideration has of

late been given to the possibility of reorganisation, co-operation, federation, and unification of the various societies devoted primarily or exclusively to promoting advance in chemical knowledge. It is, for example, scarcely fortuitous that Prof. G. T. Morgan dealt at some length with the subject in his presidential address to the Society of Chemical Industry in July, and that Prof. G. G. Henderson's presidential address to the Chemical Society in March also referred to the matter: neither were Prof. J. F. Thorpe's observations in his presidential addresses to the Chemical Society in 1930 and 1931 intended for the consideration only of fellows of that Society. Indeed, although these two chemical societies have properly taken the lead in the examination of the position and in the suggestion of methods whereby present difficulties may be surmounted and future progress assured, the problem is one which vitally concerns every chemical association and every research laboratory in the British Commonwealth.

Naturally enough, delicate and complex considerations arise with every suggestion of reunion or federation—two methods whereby considerable economy in administrative costs without contraction in scientific services might be anticipated—but encouragement is to be found in the manner in which these difficulties are being examined and discussed. Moreover, confidence arises from the fact that, for the past eight years, a substantial measure of joint operation has been successfully achieved in connexion with the publication of abstracts of chemical literature. It is well known that, by the establishment in 1924 of the Bureau of Chemical Abstracts, a body composed of representatives of the Chemical Society and the Society of Chemical Industry and charged with the production of a comprehensive and world-wide survey of current researches in both pure and applied chemistry, substantial economies have been rendered possible, while at the same time the ever expanding literature of the science is summarised and indexed with commendable accuracy, promptitude, and completeness. There can be few among those conversant with the work of this undertaking, with the needs of research workers both in academic and in industrial laboratories, and with the moderate financial resources at the command of the two societies, who would not declare this experiment in co-operative enterprise to be an unqualified success; indeed, we are unaware of any suggestion having been made that the older procedure, with its inherent lack of co-ordination and inevitable duplication, should be resumed. Few, too, would contest the desirability, in general, of a wider measure of co-operation in which other societies would participate, in order that efficiency might go hand in hand with elasticity and stability, and that the financial clouds which obscure clear vision of the future and cause anxiety for the continued supremacy of British Chemical Abstracts might be dissipated once and for all.

In his address Prof. Morgan quoted some pertinent facts and equally instructive figures; even if we admit that the exact significance of both depends on the point of view, we are still constrained to point out the inequity of so severe a task—albeit but part of the whole duty of publication—being left on the shoulders of two out of perhaps sixteen societies which are devoted to the furtherance of chemistry in one or other of its branches. Earlier this year Prof. Henderson referred to this circumstance with commendable frankness. "On these two societies alone", he said, "falls the financial burden of this great work, work which is for the benefit of every chemist in the country. It is singular and anomalous that hundreds, perhaps even thousands, of professional chemists exist here, who make no contribution to this burden, who do nothing to help the cause of chemistry in the way that is most urgent, most necessary, and most expensive." Likewise Prof. Thorpe in 1931 said: "The burden of publication now falls almost exclusively on the Chemical Society and the Society of Chemical Industry, and although it is probably correct to assume that the Journals of these Societies are of interest chiefly to their members, such an assumption cannot be made in the case of the Abstracts, which ought to be of interest to all chemists, and ought to be supported by all chemists." Indeed, we would go even further and submit that the fundamental importance of chemistry to our national prosperity lays upon the State itself the duty of rendering timely assistance in this matter.

We come, therefore, to the following conclusions: First, that the present financial circumstances of the chemical societies of Great Britain demand either curtailment of services to chemists of all descriptions, or some countervailing form of retrenchment. Second, that the reduction in administrative expenses which in the course of time would follow unification or some form of very close association would assist in removing these financial difficulties, and would at the same time promote solidarity and efficiency. Third, that a substantial experiment in joint publication has proved successful over a considerable period. Fourth, that the cost of, and responsibility for, certain

essential activities ought to be shared more widely. Taken together, they present an almost unanswerable case for amalgamation or federation, although of course they do not indicate exactly how it is to be achieved. As Prof. Morgan has pointed out, advocates of reunion have to face the fact that certain kindred societies have a mixed membership, consisting only partly of chemists; yet this has not deterred the Faraday Society and the Chemical Society from entering into conversations with the view of undertaking joint publication representative of physical chemistry in Great Britain. It has also been suggested that the news section of *Chemistry and Industry* should be published by a combination of the main chemical associations, and should be " an outward and visible sign of the reunion to which many of us aspire ". " Is it not high time ", asked Prof. Morgan, " that we evolved a considerable chemical organisation with a comprehensive chemical journal worthy of that community of nations known as the British Empire ? "

Many of us, while not pretending that geographical boundaries can circumscribe the sciences, feel strongly that the national consciousness of British scientific achievement might with advantage be stimulated in this way and by other like means. " Chemistry House ", which would have commanded public interest, was conceived as a means whereby the various societies representing chemistry and allied subjects might be brought into close physical association, so that certain activities, such as the library and a bureau of information, might be conducted jointly. Unfortunately, the project was born into a world of financial, political, and economic unrest, which soon became a panic, and the scheme must now submit to rebirth in less troublous times. Here again is a plan which carries with it the certainty of eventual economic advantage combined with that increase in effective service which cannot fail to accompany centralisation and the multiplication of opportunities for co-operation, if indeed it does not lead to the actual regrouping of chemical societies in larger units.

It ought not to be impossible by other methods, however, to secure a substantial part of the economies adumbrated by the " Chemistry House " scheme, and to do so relatively cheaply and without pressing the thorny questions of amalgamation or autonomy to an immediate decision. With this aim Sir William Pope, in a communication to *Chemistry and Industry*, recently proposed that Mr. E. R. Bolton, Dr. L. H. Lampitt, Prof. G. T. Morgan, Prof. J. C. Philip, Mr. J. Davidson Pratt, Dr. F. L. Pyman, and Mr. W. Rintoul, as representing the principal societies concerned, should be asked to constitute a committee which would consider how the resources of the various bodies concerned with the professional and scientific welfare of chemists can be most economically and efficiently utilised. If, for example, administration could be concentrated under one head in one building, the Chemical Society's library and rooms at Burlington House continuing to be the chief centre of scientific and technical activity, substantial mutual advantage would doubtless result.

But why, it may be asked, should these considerations of unity or separation, of co-ordination or non-co-operation, of economy or stringency, be regarded as matters of interest to citizens outside the ranks of the chemical profession ? Why, we might reply, were the conversations at Ottawa of interest to others besides professional politicians and economic theorists ? At least they have this in common : that the science of chemistry and the science of government, each depending for its operation and extension on a highly trained 'civil service ' and on adequate and accurate information, are both deeply concerned with the resources of the British Empire and with the use that we and our fellow-subjects overseas can make of them. " The time is ripe ", Prof. Morgan said, " for a systematic study of the material resources of the British Empire, and this task is mainly a chemist's job. Many of the natural products of the Dominions and Dependencies are in need of intensive chemical investigation. To carry out such researches in a thoroughly effective and comprehensive manner needs the expert organisation which could be best supplied by a central body fully representative of British chemistry. Every branch of chemical science would have an essential part to play in this great undertaking."

Benjamin Franklin

The Ingenious Dr. Franklin : Selected Scientific Letters of Benjamin Franklin. Edited by Nathan G. Goodman. Pp. xi + 244. (Philadelphia : University of Pennsylvania Press ; London : Oxford University Press, 1931.) 15*s*. net.

CENTENARIES are fashionable nowadays, and certainly the bicentenary of the Philadelphia Library is a day to be marked with a white stone. Franklin's restless and versatile mind was ever occupied with schemes for human betterment, and one of the most beneficial of his many beneficent deeds is perpetuated in the inscription telling us that " . . . the Philadelphia Youth [then chiefly

artificers] . . . in MDCCXXXI . . . cheerfully, at the instance of Benjamin Franklin, one of their number, instituted the Philadelphia library ".

Franklin's activities and personality are buried in some ten volumes of his collected works. One-volume editions of his life and works have seen the light—the reviewer possesses one published at Bungay in Suffolk in the early years of the nineteenth century, but he is unacquainted with any modern critical selection, and the choice of the year 1931 to give to the twentieth-century reader some notion of the many-sidedness of Franklin's genius was a very happy one.

To the reviewer's mind, the execution of the idea is somewhat imperfect—to confine the volume to a selection from the scientific letters alone is to give a very lop-sided picture of the career and character of Franklin. And an amazing picture it is, even for a society so homely that we find the Governor of Pennsylvania hobnobbing in a tavern over a bottle of madeira with an obscure printer's apprentice, even for an America of such incredibly minute dimensions that Franklin's brother was accounted over-daring in initiating the *New England Courant*, the *three* already existing newspapers being regarded as more than sufficient for the needs of the continent. That picture is not brought out by a perusal of the letters alone, and our ideal Franklin memorial volume must certainly contain, to begin with, the autobiography, complete and unabridged.

The study of a personality is always fascinating, and Franklin's autobiography opens to us a masterful, sententious, frugal, and inquiring mind, a mind which, none the less, appreciates and sympathises with human weaknesses and is not afraid to chronicle its own lapses. Truth to tell, some of Franklin's endeavours to cultivate the morals, major and minor, are apt in these days to raise a smile. He would indeed be an exceptional youth who should to-day draw up a schedule of thirteen virtues wherein to test himself, concentrating each week on one particular merit, and endeavouring to keep the daily squares allotted to it free from the black marks which indicate a lapse. Yet Franklin conscientiously carried out such a programme, completing it in thirteen weeks, and repeating it four times in a year. The schedule reproduced shows the results of a week's analysis, during which he had elected to concentrate on temperance.

A carping critic may find something of smugness in such a record, which is not apparent to those who know the autobiography in detail; it is not all a tale of achievement, and some of us can sympathise, ruefully enough, with Franklin's efforts to cultivate order and method, and his resolve at times to be content with a second-best.

TEMPERANCE

"Eat not to dullness; drink not to elevation."

"Like the man", as he himself says, "who, in buying an axe of a smith, my neighbour, desired to have the whole of its surface as bright as the edge. The smith consented to grind it bright for him, if he would turn the wheel; he turned, while the smith pressed the broad face of the axe hard and heavily upon the stone; which made the turning of it very fatiguing. The man came every now and then from the wheel to see how the work went on; and at length would take the axe as it was, without further grinding. 'No,' said the smith, 'turn on, turn on, we shall have it bright by and by; as yet it is only speckled.' 'Yes,' said the man, 'but *I think I like a speckled axe best*.'"

There are many of us who, in higher virtues than that of order, find that we like a speckled axe best.

The reader of the autobiography will find it not without interest to turn over the pages of the confessions of Rousseau, who was writing at about the same period as Franklin. The outpourings of such an introspective Heautontimorumenos as Jean Jacques differ *toto cœlo* from the calm record of Franklin. The extraordinary incident of the kettle, the story of the stolen riband, and the adventure of Madame de Warens are part and parcel of the fascinating, if sometimes repellent, character of Rousseau; Franklin's lapses from the major virtues, faithfully chronicled as they are, are but passing incidents in a life devoted whole-heartedly to the advancement of knowledge and to the practical betterment of mankind.

His long life, stretching from 1706 until 1790, saw many changes; none more striking than the metamorphosis of the printer's apprentice of 1718 to the Minister-Plenipotentiary to France of 1778, and the President of Pennsylvania of 1785. Any adequate volume dealing with Franklin must trace

this change, and it can nowhere be better followed than in the autobiography which takes us to 1757, and in a discreet abridgment of Jared Sparks' continuation of the autobiography.

The selections in the admirably printed and produced volume before us illustrate sufficiently well the varied nature of Franklin's scientific work, and the practical character of his genius. We see him designing lightning rods and bifocal lenses; discussing the best form of stove fireplace; observing the effect of oil in stilling waves—an experiment Franklin first performed on a pond on Clapham Common—and carrying, "whenever I went into the country, a little oil in the upper hollow joint of my bamboo cane, with which I might repeat the experiment as opportunity should offer"; mounting musical glasses, suitably tuned by filing, on a common horizontal spindle which could be worked by a treadle, and thus devising the instrument called the armonica; sending up his kite of cedar-wood and silk fabric, with a key at the lower end of the string, into a thunder-cloud, and—hardy fellow—telling his correspondent that "when the rain has wet the kite and twine, so that it can conduct the electric fire freely, you will find it stream out plentifully from the key on the approach of your knuckle"; giving lessons in the art of swimming, in the art of procuring pleasant dreams, and, generations before the advent of *Nacktkultur*, rising early and sitting in his chamber "without any clothes whatever, half an hour or an hour, according to the season, reading and writing".

Eripuit caelo fulmen, sceptrumque tyrannis. There is much in this volume concerning the wresting of the lightning from heaven (though there is a strange omission of the important letter to Peter Collinson of September 1753), much which illustrates Franklin's minor scientific activities. But we miss the familiar dialogue between Franklin and the Gout; we miss the sententious aphorisms of Poor Richard, and the story of the whistle; we miss those letters which reveal Franklin as a statesman and, in particular, the details of his examination before the House of Commons in 1766 relative to the repeal of the American Stamp Act.

It is, of course, entirely within the province of an editor to delimit the area of his selections, and the present volume is definitely a selection of scientific letters, which provides most interesting and varied fare for the reader. Nevertheless, one cannot but feel that an opportunity has been missed, and that the ideal one-volume edition on Franklin still remains to be published.

ALLAN FERGUSON.

The Value of Scientific Knowledge

(1) *Reason and Nature: an Essay on the Meaning of Scientific Method.* By Morris R. Cohen. Pp. xxiv + 470. (London: Kegan Paul and Co., Ltd., 1931.) 21*s.* net.

(2) *Science and First Principles.* By Prof. F. S. C. Northrop. Pp. xiv + 299. (Cambridge: At the University Press, 1931.) 12*s.* 6*d.* net.

(3) *The Logic of Science.* By Prof. Harold R. Smart. Pp. viii + 237. (New York and London: D. Appleton and Co., 1931.) 8*s.* 6*d.* net.

(1) MODERN thought undoubtedly suffers from the actual hostility between Nature and reason, which were once joined in the Hellenic ideal of science. The appeal for an effective and conscious union of these two fundamental elements of science is inspiringly illustrated in Prof. Cohen's work, which thus carries under its learned guise a constructive message to philosophers and men of science. Prof. Cohen believes neither in a conventional supernaturalism nor in a sentimental irrationalism, but he finds much inspiration in the older thinkers, and he is thus led to make this modest but useful, if not heroic, pronouncement: "The philosopher, whose primary interest is to attain as much truth as possible, must put aside as a snare the effort of originality. Indeed, it seems to me that the modern penchant for novelty in philosophy is symptomatic of restlessness or low intellectual vitality." It is in this spirit of a true friend of wisdom that he surveys the general meaning of the principles of procedure according to which scientific results are obtained and according to which these results are being constantly revised.

In the first part of the book, Prof. Cohen deals with the mental attitudes, such as historicism, psychologism, authority, pure experience, intuition, and creative imagination, which seem to guide the modern research worker. The two remaining parts are devoted to an analysis of natural science, including biology and psychology, and of social science, with special reference to the postulates of reason.

Taking at random one example of Prof. Cohen's inquiry—that which deals with the nature of mathematics—we find him discussing the logical character of pure mathematics, their relation with intuition, and the important question of how applied mathematics is possible. His general conclusion is that the relational structure of mathematics, which is their very object, is just as objective as the physical entities related; and that the laws of mathematics are applicable, because they are the

laws according to which all objects or realities can be combined. The assumption that numbers and mathematical or logical laws are mental is due, according to Prof. Cohen, to the "vulgar prejudice" that only particular sensible entities exist in Nature, and that relations, abstractions, or universals cannot have any such objective existence. "But this is a shabby subterfuge: for these numbers or relations are also numbers and relations of things; and any assertion with regard to these abstractions is either true or not. Now truth, whatever it is, is not a quality which inheres in a proposition simply because it is mental, but a proposition is true because of factors other than the fact that I now think this proposition" (p. 203). It follows that logic and pure mathematics apply to Nature because they describe the invariant relations which are found in it; and thus they enable us to extend our knowledge of Nature by supplying us with illuminating perspectives and by insisting on relevance which is a condition of sanity.

(2) A similar attitude, but perhaps with a more pragmatic inclination, seems to be adopted by Prof. Northrop in discussing the claims of modern theoretical science. He also thinks that the complexity, richness, and beauty of the scientific, æsthetic, and religious experience find their source in the happy combination of these three fundamental principles: the primacy of motion, the source of rationality and necessary order in the physical referent for motion, and the identification of the purely psychical with bare indeterminate experienced quality. This view leads Prof. Northrop to describe reality, as known by scientific philosophy, as æsthetic immediacy with its physical, formal, and psychical conditions made specific. As an example of his conception of the standard thinker, he gives us Leonardo da Vinci, for whom "the physical and the formal were grasped without being torn from the vivid psychical immediacy in which both are embedded".

The importance of these general ideas is illustrated by some very interesting considerations on certain specific scientific theories, such as the theory of relativity, the quantum and wave mechanics, and the fundamental principles of biology and anthropology. For example, in discussing the various aspects of the theory of relativity, Prof. Northrop suggests that the conclusions reached in connexion with the necessary consequences of the theory, if properly treated, should possess equal certainty, since they merely designate what else must be true if the theory is true. But he holds that the theories of the finite universe of Einstein and de Sitter, and the unitary field theories of Weyl, Eddington, and Einstein, rest on more questionable assumptions, and lack the experimental verifications which Einstein's earlier discoveries enjoy. Thus Prof. Northrop is led to think that the physical theory of Nature in a kinetic atomic form must be true; for after introducing and recognising more relativity than even the most imaginative speculative mind has ever conceived, Einstein's discoveries reveal that there is something absolute in Nature, remaining objective and invariant through all the relativity which exists, and that this absolute factor is matter and motion.

(3) The necessity of hanging the bulk of our scientific knowledge to something real, something absolute beyond the fact of perception, is also prominent in the analysis of the sciences proposed by Prof. Smart. His object is to answer some pertinent questions which arise necessarily in one's mind when one contemplates the lofty achievements of modern science. Is mathematical knowledge the product of pure thought functioning apart from all experience? Should we say that physics is a branch of geometry? Or does it tell us only of a certain orderliness amongst our purely subjective perceptions? Are substance and causality outworn conceptions, no longer applicable to natural phenomena? What possible solution can be proposed to the interminable struggle between mechanists, teleologists, and vitalists in biology?

These and other queries show the range of Prof. Smart's considerations. Generally speaking, he is of opinion that a *via media* suggests the best solutions to these fundamental problems with regard to biology; for example, he believes that in the biological sciences, the conception of natural kinds dominates the search for laws, somewhat as physical conceptions condition the application of mathematical principles to physical phenomena. As for mathematics, Prof. Smart suggests that the mathematician shares with other natural scientists the content supplied by the world of existential phenomena. The hypothesis of pure mathematics being a completely *a priori* science, functioning apart from all experience, is denounced as the enemy of all science and philosophy, because it lands us into all sorts of impossible dualisms and irresolvable contradictions.

Reaching by degrees the universal plane of philosophy, Prof. Smart contends that scientific knowledge constitutes itself a revelation not only of Nature, but also of mind itself, which presupposes, however, the independent existence of Nature. Consequently, a law of Nature ultimately implies both an objective order of which it is a representa-

tion, and a principle of intelligibility of which it is an expression. It follows that the task of philosophy involves the differentiation and integration of these several values in a systematic unity.

There is no doubt that the considerations put forward by these three writers will make a wide appeal to those whose experience in the field of speculation has led them to believe that present-day science seems to be struggling along against a sense of unreality. Extreme views in the interpretation of our scientific knowledge can be useful during a certain time, for they suggest new problems, novel solutions, and original methods of approach. But they can scarcely hold the field permanently; and the time now seems to have come when some kind of reasonable unification is desirable. This unification is the more important as the general crisis in which our society appears to be involved can scarcely find a satisfactory solution if leaders of thought are not certain amongst themselves as to the real value of their knowledge.

THOMAS GREENWOOD.

Furs and Feathers

Die Rohstoffe des Tierreichs. Herausgegeben von Ferdinand Pax und Walther Arndt. Lief. 6. Pp. 449-576. 12 gold marks. Lief. 7. Pp. 577-736. 16·20 gold marks. Lief. 8. Pp. 737-880. 14 gold marks. (Berlin: Gebrüder Borntraeger, 1931.)

IN the sixth part of this work the account of the fur-bearing animals is completed. It is satisfactory to note that the colony of seals on the Pribilof Islands is increasing and comprises about a million individuals. In 1929 about forty thousand skins of this seal were collected. The order Carnivora is stated to include the largest number of species of fur-bearers and to provide the most costly skins—for example, those of the American fox, the finest examples of which from the Hudson Bay region, Labrador, and Alaska, are worth 50-400 marks each, and about 250,000 a year are sold. Of the European fox, about a million skins a year are collected; the Norwegian examples command the highest price, about 100-150 marks. The dearest fox skin is that of the silver fox, the finest specimens of which come from Labrador and have been known to realise up to 6000-8000 marks a skin.

The account of the Karakul sheep, the skin of which is known in commerce as 'Persian', includes reference to the lamb-skins of this species. The small skins, often spoken of as those of unborn lambs, are the skins of lambs the mothers of which died at or shortly after their birth. The statements that the ewes are roughly treated to cause premature birth of the lambs is definitely said to be untrue, and is unlikely, as the ewes are worth 100-150 marks and the skins of very young lambs about twenty marks each.

The number of species of animals the skins of which form an article of commerce as furs is given as about 175. Statistics of the number of pelts sold in 1928 are given for the principal countries, and show that about a hundred million rabbit skins were marketed in Europe and a similar number in Australia; in fact, that about sixty per cent of the skins coming on the market were those of the rabbit, which reached a total of 209 millions. The next in order of number were the hare, 32 millions; sheep, 30 millions; mole, 21 millions; squirrel and musk-rat, 17 millions each. The total value of the world production of rough skins in 1928 was about £77,000,000.

A chapter of twenty-four pages gives a useful summary of present knowledge and practice in the raising of fur-bearing animals, which has in recent years assumed considerable importance. The number of such farms at the end of 1929 in Germany was about five hundred, and there is corresponding development in many other countries. The principal animals reared are the silver fox, blue fox, mink, raccoon, skunk, and musk-rat—the last especially in Canada. Details of the layout and working of some of the farms are given. The spread of the musk-rat in Germany is graphically illustrated by a map which shows the rapid extension of its range between 1907 and 1924. This species has become a serious nuisance in Germany and has caused damage in central Scotland.

The seventh part and nearly the whole of the eighth part of this work are devoted to an account of the skins and feathers of birds, the orders of birds being considered in systematic sequence. The methods of treating skins and feathers to improve their appearance and to destroy the parasitic insects and mites are described, and the extent and value of the ornamental feathers and skins imported into Germany, England, and other countries are shown in statistical tables. A separate section is devoted to the skins and feathers of ostriches (there is only a relatively small trade in those of the South American rhea and a quite inconsiderable trade in those of the Australian emu and cassowary) and to ostrich farming. The difference between the number of ostriches in the Union of South Africa at the end of 1913 (776,313) and in 1926 (104,578) bears striking testimony to the influence of fashion. The

essentials of a good ostrich feather and the defects —for example, 'barring'—are noted, and statistics are added of the number and value of the feathers produced.

In the section on feathers for beds—obtained chiefly from ducks, geese, and hens, in many cases as a by-product—and on down, many details are given of their physical properties and of their preparation for their principal uses. The various uses of feather-quills and the employment of feathers and bird-skins for ornament by native peoples are described. This section concludes with a very useful summary of the species of birds the skins and feathers of which are of commercial value, with a note of their geographical distribution.

Bibliographies are appended to the principal sections, and interesting illustrations, chiefly from photographs, are placed in the text. This work presents, in concise and well-arranged form, up-to-date information, both scientific and commercial, on the skins of mammals and birds, and can be recommended as an authoritative source of reference.

Short Reviews

Die natürlichen Pflanzenfamilien: nebst ihren Gattungen und wichtigeren Arten, insbesondere den Nutzpflanzen. Begründet von A. Engler und K. Prantl. Zweite stark vermehrte und verbesserte Auflage, herausgegeben von A. Engler. Fortgesetzt von H. Harms. Band 19*a*: *Angiospermæ, Reihe Pandales.—Reihe Geraniales, Unterreihe Geraniineæ (erster Teil).* Redigiert von F. Pax. Pp. iv + 470. 60 gold marks. Band 19*c*: *Angiospermæ, Reihe Geraniales, Unterreihen Dichapetalineæ, Tricoccæ, Callitrichineæ.* Redigiert von F. Pax. Pp. iv + 251. 32 gold marks. (Leipzig: Wilhelm Engelmann, 1931.)

THE publication of the new edition of "Die natürlichen Pflanzenfamilien", which has been supervised, since the death of Engler, by Dr. H. Harms of Berlin, is progressing steadily, two volumes, namely, 19*a* and 19*c*, having appeared during 1931. Vol. 19*a* begins with the monotypic order Pandales, based on *Panda oleosa* Pierre, a West African forest tree of uncertain affinity. This is followed by ten families of Geraniales, from Oxalidaceæ to Burseraceæ respectively. More than a third of the volume is occupied by the account of the Rutaceæ, which, together with those of Zygophyllaceæ, Cneoraceæ, Simarubaceæ, and Burseraceæ, was prepared by the late Prof. Engler. The great extent of recent research on the Rutaceæ is reflected in the number of genera now recognised in that family, 145 as compared with 111 in the first edition. This is due partly to extensive generic segregation in the subfamily Aurantioideæ by Swingle and others. Both text and figures are much blacker than in the first edition, the figures in some cases—for example, *Casimiroa edulis* (p. 305)—being far too heavily shaded. Most of them, however, are very clear.

Vol. 19*c* is mainly taken up by the account of the Euphorbiaceæ, by Pax and K. Hoffmann. This great family now includes 283 genera, as compared with 209 in 1890, and the introductory matter has been thoroughly revised, now extending to 31 pages instead of 13. The necessity for a second edition is therefore obvious. In this volume also many of the illustrations—for example, *Mallotus philippinensis*—are, unfortunately, far too black.

Under the general direction of Dr. Harms, the high standard of the first edition is, on the whole, maintained.

Hume's Philosophy of Human Nature. By Prof. John Laird. Pp. x + 312. (London: Methuen and Co., Ltd., 1932.) 12*s*. 6*d*. net.

HUME becomes more and more popular among philosophers. The reason is that we find ourselves in a period very similar to his. Indeed, it is felt that the dogmatic interpretations which have been given of the momentous discoveries of our time are not quite satisfactory in themselves. Before proceeding to the formulation of new theories, it appears necessary to clear the ground, which implies primarily the action of a sceptic mind. It is quite natural, then, that philosophers should turn for inspiration and encouragement to David Hume, the father of modern scepticism.

Though Hume was versed neither in mathematics nor in natural science, the critical examination he made of their theoretical presuppositions is a permanent addition to our philosophical knowledge. His great contribution to the discussion is his distinction between 'knowledge' and 'probability', which is at the basis of inductive inference.

Prof. Laird explains and examines Hume's principles of causal inference in Chap. iv., perhaps the most important of his book. There we find a remarkable discussion of questions such as the uniformity of Nature, belief, testimony, conjectural probability, analogy, and experimental method, where Hume anticipates many considerations which we find later in Stuart Mill's "System of Logic". One of Hume's most peculiar principles is that which denies plurality of causes and plurality of effects, though it may be doubted whether he was entitled to hold it without any decisive arguments. In his chapter about "Space, Time, and External Existence", Prof. Laird discusses also many interesting doctrines of Hume's bearing on the foundations of mathematics. His long acquaintance with Hume's system has made Prof. Laird one of the safest guides to the complexities of his philosophy; and the book he has produced is a permanent addition to the philosophical literature of the day.

Volumetric Analysis. By G. Fowles. Pp. xii + 202. (London: G. Bell and Sons, Ltd., 1932.) 6*s*.

THIS book will be welcomed by teachers of chemistry who are desirous of placing in the hands of their students a lucid exposition of up-to-date methods of volumetric analysis. Although intended for uni-

versity students and candidates for university scholarships and the National Certificate in Chemistry, the book contains much matter which will be of interest to many chemists.

Mr. Fowles has been at considerable pains to expound the principles upon which volumetric analysis is based, so that in carrying out the determinations the student will be consciously applying these principles and not merely performing a set of experiments without regard to the physico-chemical theories involved.

The first two chapters are devoted to general principles, and include much information on equivalents, indicators, calibration, and the selection of substances as standards. The next four chapters deal with the various methods of volumetric determinations—neutralisation, in which the theory of indicators is discussed; oxidation by permanganate, dichromate, bromate, and iodate; reduction by titanous sulphate; iodometry; and precipitation. The final chapter takes the form of a synopsis, and contains the volumetric processes for the estimation of all common metals, acid radicals, and many organic compounds.

Embodying, as this book does, the recent advances in volumetric analysis, it is a very useful addition to chemical literature.

Why we Oppose the Occult. By Prof. Émile Cailliet. Translated by Prof. G. F. Cole. Pp. v + 200. (Philadelphia: University of Pennsylvania Press; London: Oxford University Press, 1931.) 8*s*. 6*d*. net.

To the modern mind the very word 'magic' stands for an idea which is little short of degrading. Yet we have to remember that, according to high authorities, magic was the real foundation of religion, the most divine creeds having belief in magic as their basis. Furthermore, the ancient Oriental magicians passed on their accumulated observations to the Greeks, enabling the latter to lay the foundations of mathematics, so that magic may be said to be the origin of science—of science through the intermediary of religion, as Frazer shows. But societies which thus owe so much to magic not only free themselves from it, but also vigorously reject it, turning from the occult with disgust. In our own day the occult is the object, not merely of disbelief, but also of active opposition and ridicule. Why? That is the problem to which Prof. Cailliet addresses himself in this book, with many examples drawn from his intimate knowledge of beliefs and practices in Madagascar.

Physics: Fundamental Laws and Principles with Problems and Worked Solutions. By Edgar Booth and Phyllis M. Nicol. Pp. 648. (Glebe, N.S.W.: Australasian Medical Publishing Co., Ltd., 1932.) n.p.

This volume, which is of a good intermediate standard, is divided into two main sections. The first part consists of thirty-six chapters, and expounds the fundamental principles and laws of physics in a series of clear statements which are driven home by means of a large number of illustrative problems, of a mixed bookwork and rider type.

The second part consists of answers to and worked solutions of the problems given in the first part.

The whole book bears evidence of much care and thought in its preparation; it should prove a useful aid in testing and co-ordinating the knowledge of a student of elementary physics.

The Doctor Explains. By Ralph H. Major. Pp. xvi + 277 + 27 plates. (London: Chapman and Hall, Ltd., 1932.) 15*s*. net.

It would be difficult to present a more interesting and comprehensive account of progressive medical science and practice than that covered by this book. The author succeeds brilliantly in his endeavour to explain in untechnical language how the methods of treatment and diagnosis employed by modern physicians and surgeons are the results of research in many scientific fields, and his work should do much to promote intelligent interest in the preventive as well as the curative services of medicine. The book is an inspiring record of human thought and action towards the conquest of disease, and it will be read with both profit and pleasure not only by the laity but also by many general medical practitioners.

Hippokratesglossare. Von Max Wellmann. (Quellen und Studien zur Geschichte der Naturwissenschaften und der Medizin, herausgegeben vom Institut für Geschichte der Medizin und der Naturwissenschaften, redigiert von P. Diepgen und J. Ruska, Band 2.) Pp. iv + 88. (Berlin: Julius Springer, 1931.) 16 gold marks.

This learned memoir is a valuable addition to the history of the sources of the Hippocratic commentators. The main point of its author is that Erotian, who wrote a glossary on the Hippocratic works during Nero's reign, was not a grammarian, but a physician. Then he goes on to discuss the sources of Erotian, and to compare previous glossaries of the Hippocratic works with them. The glossary of Bakcheios, who published the first edition of the Hippocratic works, was superseded later by the commentaries of Glaukias, Epikles, Heraclides of Tarentum, and Euphorion the Grammarian.

Die lichtelektrische Zelle und ihre Herstellung. Von Dr. Richard Fleischer und Dr. Horst Teichmann. Mit einer Einführung von Prof. Dr. H. Dember. (*Wissenschaftliche Forschungsberichte, Naturwissenschaftliche Reihe*, herausgegeben von Dr. Raphael Ed. Liesegang, Band 27.) Pp. xii + 175. (Dresden und Leipzig: Theodor Steinkopff, 1932.) 12 gold marks.

This unpretentious little volume gives, in compact and handy form, a very clear conspectus of the properties and methods of production of light-sensitive cells. It is well produced and illustrated, and its usefulness is enhanced by a critical bibliography of some 230 entries, ranging over the years 1877–1931.

Physical and Observational Evidence for the Expanding Universe

By J. H. REYNOLDS

SO much has been written in recent years on the subject of the expanding universe from the theoretical point of view, that there is no need here to give more than a summary of the position, following Sir Arthur Eddington. The 'Einstein universe' was a conception based on a static solution of Einstein's field equations in which matter was distributed with uniform density, filling a closed space, and in equilibrium owing to the balancing of gravitational attraction and cosmical repulsion. In 1917, Prof. W. de Sitter, of Leyden, put forward his now famous hypothesis, predicting large velocities of recession for distant objects, which was based on a small modification of Einstein's equations. The difficulty about the 'De Sitter universe' was that it was empty, so that the cosmical repulsion acted without hindrance.

The discovery, mainly owing to V. M. Slipher, that the line shifts in the spectra of the spiral nebulæ were large and predominantly towards the longer wave-lengths, lent a considerable measure of support to de Sitter's theory, but obviously the universe was not empty of matter, and some other intermediate solution had to be sought. Such a solution was found ultimately by Abbé G. Lemaître in 1927, although its importance was overlooked until de Sitter and Eddington directed attention to it in 1930. They realised at once that a non-static solution of the Einstein equations was possible, so that an expanding or contracting universe was inevitable from Einstein's law of gravitation. The question whether contraction or expansion would best agree with the conditions actually existing was considered settled by the observed displacements of the nebular absorption lines towards the longer wave-lengths, which on the Doppler principle would be interpreted as measures of velocities of recession.

The observational evidence required to establish the hypothesis, and to evaluate the expansion factor, lay in two separate series of data: (1) an adequate number of measured spectra of the extra-galactic nebulæ with as wide a range of systems as possible, and (2) a trustworthy scale of distances for these systems.

RADIAL VELOCITIES DERIVED FROM THE LINE DISPLACEMENTS IN THE SPECTRA

From the instrumental point of view, the difficulties of securing satisfactory spectra for measurement were at first considerable. The spectrographs employed for stellar work and for galactic nebulæ giving bright line spectra proved quite inadequate to deal with the faint continuous spectrum of the extra-galactic spiral and elliptical nebulæ, even with prolonged exposures.

The obvious remedy was to reduce the dispersion, although this made wave-length measures more uncertain, and it was not until a scale of about 100 A. to the millimetre was adopted that satisfactory densities were obtained, with exposures from twenty to thirty hours spread over several nights.

The type of spectrum of the extra-galactic nebulæ was found in general to be very similar to the solar spectrum, the principle lines being the *H* and *K* lines of calcium, and the *G* group, with some traces of the hydrogen lines, all appearing as wide and shallow absorption lines on a continuous spectrum.

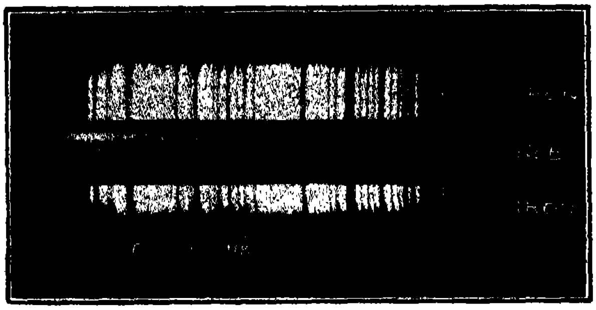

FIG. 1.—Dark-line spectrum of nebula M 81 (N.G.C. 3031) by M. Wolf, Heidelberg.

The first list of forty measured spectra was issued by V. M. Slipher about ten years ago. Among these a small group, including the Andromeda Nebula and M. 33 (the two spirals of largest angular size in the sky and probably the nearest) were found to have large displacements towards the shorter wave-lengths, and therefore considerable velocities of approach. These, with one exception, were all in the south galactic hemisphere in the same region of the sky.

On the face of it, this seemed to raise a serious difficulty, for, according to the hypothesis, it was impossible to have expansion and contraction existing together. The discovery later of the rotation of the galaxy by Dr. Oort, and its subsequent confirmation, furnished a simple explanation of these negative velocities, as the term introduced was a large one, about 280 km./sec., and in the right direction. At the same time, it is as well to state that considerable discrepancies have occurred in the measures of the nearer as well as the farther nebulæ. As an example of this, the first measures of the radial velocities of the Andromeda Nebula and M. 33 gave values of −300 km./sec. and −260 km./sec. respectively, while the latest measures of these two spirals give much smaller values, namely, −220 km./sec. and −70 km./sec.

If the galactic rotation is responsible for these velocities of approach in the south galactic hemisphere, one would expect a similar effect on the nearer spirals of large apparent angular diameter in the north galactic hemisphere, so long as they are similarly situated in galactic latitude and longitude. There are two objects which conform to these conditions, M. 81 (N.G.C. 3031) and N.G.C. 2403. The velocity shift of the first has been measured and is of the right order, −30 km./sec. N.G.C. 2403,

which should show a much larger negative velocity from its position, has not yet been included in the lists of radial velocities.

Since 1928 the question of line displacements has been taken up at Mount Wilson by Hubble and Humason, and the number of known displacements very greatly extended by the inclusion of fainter, smaller, and more distant objects. Special spectrographic apparatus had to be contrived for dealing with these faint nebular images in the 100-in. reflector. For some of the previous work a dispersion of 170 A. per millimetre was found to be concentrated enough, but this was replaced by a dispersion of 340 A. per millimetre.

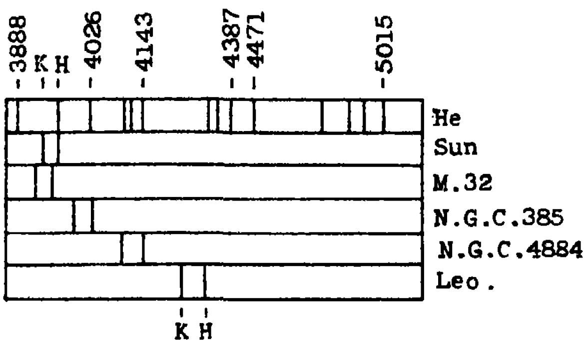

FIG. 2.—Measured displacements of the *H* and *K* lines.

In its turn, this also was discarded for an even smaller dispersion for very faint nebulæ. With a spectrograph objective of F/0·6 designed by Dr. W. B. Rayton, two prisms gave a dispersion of about 418 A. per millimetre at λ4500, and one prism 875 A. per millimetre. The uncertainty of the result with the last-named is claimed to be not greater than 300 km./sec., which is small compared with the line displacements. The highest velocity yet measured was found in a cluster of small elliptical nebulæ in Leo, where the displacement in the brightest member was equivalent to the stupendous rate of +19,700 km./sec.

The small scale of the spectrum is naturally a disadvantage so far as measurement is concerned, but a well-defined comparison spectrum of helium above and below the nebular spectrum gave a series of wave-length positions quite accurate enough for the purpose.

THE DISTANCES OF THE EXTRA-GALACTIC NEBULÆ

The great difficulty in correlating the radial velocities derived from the spectra with distance has been the lack of a definite scale of distances. Until a few years ago, even the order of distance was only a matter of conjecture, but the discovery by Hubble of Cepheid variables in the outer regions of the Andromeda Nebula gave at last a basis for a definite estimate of the distance of this system.

The previous work of Shapley and others had shown that a relationship existed between the absolute magnitude of these stars and their period. Those of short periods of a day or less are of considerably less intrinsic brilliancy than those of much longer period. All the Cepheids found by Hubble were of the longer periods, corresponding to the stars of greater absolute magnitude, those of shorter period being presumably too faint to be detected. As a first approximation the distance of the Andromeda Nebula was determined as a million light-years, and a similar investigation of M. 33, a neighbouring formation in the sky containing well-defined masses of stars, led to a slightly less distance. The Cepheid variables are undoubtedly the most reliable guide to distances, but there are other types of stars to which absolute magnitudes can be assigned within wider limits. Such are O type stars of very high surface temperatures, B type of temperatures of about 15,000 C., novæ which have occurred from time to time in the nuclear regions, and others. These were also found to exist in the two nebulæ mentioned. Linked up with the Cepheids they gave a reasonably consistent result. Estimates of these and other spiral and elliptical nebulæ were also made by Lundmark of Uppsala and agreed in general with those obtained by Hubble.

Later a list of the eight nearest nebulæ was compiled by Hubble, based on magnitude observations

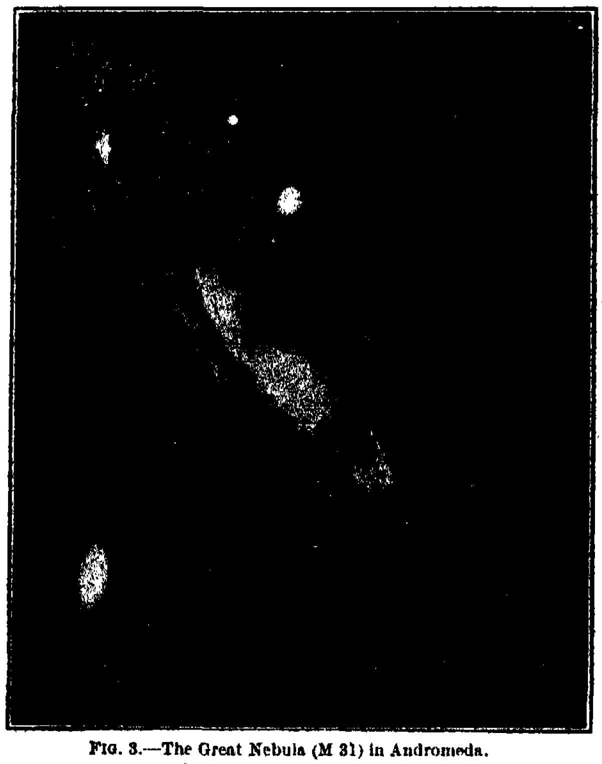

FIG. 3.—The Great Nebula (M 31) in Andromeda.

of involved stars of known types and including the two Magellanic Clouds which were regarded as irregular extra-galactic nebulæ.

For more distant nebulæ in which faint stars were actually detected but the types of which were unknown, Hubble adopted the principle that there is an upper limit to intrinsic stellar luminosity, and that observed differences in magnitude of these faint stars in various nebulæ give a rough guide to differences in distance.

Unfortunately, discrete star discs can be more easily detected in the condensed or later type of spiral than those having an amorphous bright nucleus and a varying amount of outer condensation. Out of a total of 31 nebulæ of the type of the Andromeda Nebula, 19 gave negative results, while out of 30 of the condensed type of M. 101, 22 gave positive results. This means that for two objects of different types, comparable so far as diameter and distance are concerned, one would probably show star discs and the other would not.

Some other criterion, therefore, had to be adopted. The most obvious was the angular diameter, which on the average would vary directly in inverse ratio to the distance for any particular class of nebulæ.

The difficulty of getting a reliable scale of distances, either by the integrated light of the nebulæ or the diameters, is very well exemplified by taking the two spirals of largest angular diameter in the sky—M. 33 and the Andromeda Nebula (M. 31). The distances of both have been well determined by Hubble from the Cepheid variables involved, and come out as follows :

FIG. 4.—Spiral nebula M 33 photographed with 60 in. reflector at Mount Wilson.

	Distance in 10^6 parsecs.	Diameter.	Estimated Visual Integrated Magnitude.
M 33	2·36	80′	7
M 31	2·47	140′	5

(One parsec = 3·259 light years.)

M. 31 is thus more than half as large again in angular diameter, and its total integrated light six times that of M 33, yet it is actually more distant, although the difference is comparatively small.

Of course, if a great number of nebulæ of either the spiral or elliptical type are taken, the diameter and integrated luminosity together would give a rough scale of distances, but the distances of particular objects might be out by as much as 40 per cent.

FIG. 5.—N.G.C. 3379, a typical elliptical nebula.

Hubble and Humason prefer to adopt total luminosity alone as a criterion for the nebulæ in which no stars are visible, on the ground that while increased exposure systematically extends the linear dimensions on the plate up to a superior limit, the percentage of increased diameter is much greater than the percentage of total luminosity, as there is normally a great concentration of luminosity in the nuclear regions. But in any event, it is obvious that the great trouble in arriving at a satisfactory scale of distances is the lack of homogeneity in the observational material. Even for the same objects the integrated luminosity obtained by photographic out-of-focus images differed by as much as three magnitudes in the results obtained at Mount Wilson and Harvard respectively. In the clusters of elliptical nebulæ, which must be of the same order of distance, there is a range of four magnitudes between the brightest and the faintest, so here integrated luminosities would be anything but a sure guide.

CORRELATION OF RADIAL VELOCITIES AND DISTANCES

Notwithstanding the unsatisfactory nature of the scale of distances, Hubble established in 1929 that there is a general correlation between radial velocities and distances of something like 500 km./sec. per million parsecs. The following lists give some typical examples :

ESTIMATED DISTANCES AND EQUIVALENT RADIAL VELOCITIES OF THE EIGHT NEAREST KNOWN SYSTEMS

System.	*R.*	*V.*	*L.*	*B.*
Nubecula Major .	0·262	+170	245°	−35°
Nubecula Minor .	0·290	+290	265	−40
N.G.C. 6822 . .	1·92	−130	350	−19
M. 33 . . .	2·36	−70	101	−31
M. 31 . . .	2·47	−185	87	−22
M. 101 . . .	4·0	+200	116	+58
N.G.C. 2403 . .	6·3	..	62	+28
M. 81 . . .	7·3	−30	107	+39

R. = distance in parsecs × 10^6.
V. = equivalent velocity displacement.
L. = Galactic Longitude.
B. = Galactic Latitude.

The distances given here are based on the Cepheid variables, except the two last, where stars of other types are used as gauges.

The solar galactic rotation effect, found by Hubble to be about 280 km./sec. with its apex in galactic longitude 32° and latitude + 18°, introduces large corrections in most of the above. Taking this into account, all the negative velocities disappear, and we are left with a quantity which represents a combination of the expansion rate and the peculiar motion of the system.

In the next table the solar galactic rotation effect is smaller compared with the velocities. Representative systems only are given, as the total number now known altogether is over eighty.

Here the radial velocities have already been corrected for the galactic rotation.

The distances have been estimated from involved stars of the 18th magnitude and fainter, the types of which are unknown. These stars are taken as representatives of maximum intrinsic luminosities.

System.	R.	V_s.	Mn.	Ms.
N.G.C. 5236 .	0·9	+500	10·4	18·5
3627 .	0·9	+850	9·1	18·5
1068 .	1·0	+920	9·1	18·7
7331 .	1·1	+500	10·4	19·0
4258 .	1·4	+500	8·7	19·5
4151 .	1·7	+960	12·0	20·0

Mn = integrated nebular luminosities.
Ms = stellar magnitudes.

Past this point stars are no longer available as criteria of the more distant systems, so reliance has been placed by Hubble on the integrated visual or photographic magnitudes of the nebulæ themselves. If we take a hypothetical nebula of average total intrinsic luminosity and imagine it removed to twice the distance, its diameter would of course be halved and its total luminosity reduced to a quarter.

As the ratio between one stellar magnitude and the next is 2·512, it follows that a decrease in luminosity of one magnitude would be equal to an increase of distance by 1·58. This is therefore the equivalent ratio in the following table, where integrated magnitudes take the place of estimated distances. Large discrepancies are inevitable in such a procedure, as the results show.

As a final test of the validity of the expansion factor for very distant objects, Hubble and Humason examined certain of the brighter nebulæ which appear in isolated groups. The great majority of these are of the small elliptical type, showing no spiral structure. Some nebulæ in the Virgo group, which would perhaps be better described as a concentration in the line of sight, gave largely different velocities, but the general results were such as to give ample support to the expansion hypothesis.

From the data given, Hubble and Humason adopt a round figure of 560 km./sec. per million parsecs as the velocity-distance relation. Although the whole investigation was necessarily based on indeterminate and to some extent arbitrarily selected material, the relation seems to be a reality. The velocity ratio found can scarcely be regarded yet as more than a first approximation, but it is of the right order.

Fig. 6.—Field of elliptical nebulæ by 100-in. reflector at Mount Wilson. R.A. 3 h. 12 m. Decl. +41° 8′ (Perseus).

System.	V_s (corrected for solar motion).	Mag. Vis. or Phot.
N.G.C. 4051	740	11·9
3227	1090	12·0
7217	1250	12·3
2859	1450	11·1
2950	1560	11·6
3010	1950	11·8
6703	2280	13·6
6702	2530	14·6
6359	3250	14·3
6661	4170	14
6710	5380	15

Group.	Number.	Range of V_s km./sec.	Mean Photr. Integrated Magnitude.
Virgo . .	7	600-1170	12·5
Pegasus . .	5	3500-4000	15·5
Pisces . .	4	4460-4960	15·4
Cancer . .	2	4670-4970	16·0
Perseus . .	4	4800-5800	16·4
Coma . .	4	5100-8000	17·0
Ursa Major (Baade 24)	1	11800	18·0
Leo . . .	1	19600	19·0

A question has been raised as to the proper interpretation of the observed displacements of the

spectral lines. Is the Doppler effect the only possible interpretation? If the slowing down of light over vast distances is a possibility, shifts towards the red would be expected—indeed, de Sitter's original cosmology suggested this as alternative or complementary.

A letter to NATURE of Jan. 16, 1932, from Prof. W. D. MacMillan, suggests that the red shift is due to loss of energy in the photon in course of time, due either to inherent instability or collisions with other photons. He concludes: "Such an interpretation of the extraordinary shifts that are observed will be more acceptable to many than an interpretation which makes our galaxy a centre from which all others are fleeing with speeds that are proportional to the distances".

Canons of Archæological Theory *

By Dr. DAVID RANDALL-MACIVER

FROM a vast and intricate subject I will select for discussion only two of the principal problems of archæology—namely, the application of a time-scale and the proof of the dissemination of a culture. First, then, as to the time-scale. A series of culture periods has been well established, so that there is a reliable system of what is called 'relative chronology' from the earliest Stone Age down to the time of full documentary history. But it is a very different matter when we attempt to translate these culture periods into centuries and thousands of years. We are wholly dependent for our absolute chronology upon the dates recorded or obtained by immediate inference from ancient writings or traditions. The fragmentary relics of Mesopotamian and Egyptian official chronology furnish a time-scale, liable to much uncertainty in minor details, but trustworthy in all its main lines. As archæological discovery proceeds in the coming years, we may reasonably hope to arrive at a completely graduated scale of chronological dating in actual years for every part of the ancient world after 3500 B.C. But if it is asked what means we have for establishing a chronological as well as a typological scheme behind 3500 or possibly 4000 B.C., I answer unhesitatingly that we have none, and that unless earlier written records or traditions come to light it is probable that we shall never have any.

One very crude method of attempting to avoid this impasse is so illogical that I need spend little time in discussing it. Below the strata in which definitely datable objects are found—whether at Knossos, Ur, Susa, Mohendjodaro, or any other very ancient site—there are generally strata of a certain thickness in which other and obviously earlier forms occur. Now, it is sometimes suggested, even by skilled explorers in their less discreet moments, that the mere thickness of these undated layers may give an indication of the length of time which it took to form them. Yet a very slight amount of reflection, not to speak of actual experience in the field, will show that this reasoning is as childish as it is simple. I have myself seen in Egypt deposits many feet deep which can, nevertheless, be proved, by well-dated objects at the top and bottom, to have been formed within a single century; and I have also seen a concentrated stratum of not more than four feet which contained the products of many centuries closely pressed together.

In a less crude but not very different form, the same error appears in the attempt made by several justly admired writers to establish a chronological scale for the typological series preceding the historical in a country like Egypt. The system of sequence-dating based on typology is now familiar to all students. It was established for Egypt by Sir Flinders Petrie, and for Europe in general by Montelius. As a scheme of relative chronology it sometimes creaks a little, but on the whole it works well and has justified itself, though it may need occasional emendation. But the recurring attempts made by one author after another to translate this relative system into an absolute chronology of years have no logical justification whatsoever, and only encourage self-deception.

The argument is really based on an assumption which can easily be shown to be fallacious. This is the assumption that the rate of progress in civilisation is always uniform. If we know the rate of development in types which took place during the First and Second Dynasties and know also from inscriptions the length of these dynasties, then, it is argued, we have a yard-stick which can be applied to the period preceding the First and Second Dynasties. It is as though a policeman, having timed a speeding motor car over a measured mile, and found that it was going at sixty miles an hour, should appear before the magistrate and state that it was evident the defendant had been proceeding all day at sixty miles an hour.

If, however, we must abandon such illegitimate methods, it is not quite impossible that properly directed ingenuity may find some others which will give a rough scale, less accurate indeed than the chronological, but, nevertheless, valuable. The recent success of Miss Caton-Thompson in settling the very difficult dating of Badarian culture by truly logical methods based on geology is very encouraging; and thirty years ago I myself made a suggestion which I still think has some value. If, I suggested, we could discover the village corresponding to an ancient cemetery, and also ascertain the total number of burials in that cemetery, then we should be able by calculating the presumable death-rate to arrive at a rough estimate of the number of generations. It is evident that several factors in this equation can never be established more than approximately, but it would be worth attempting, if ever a suitable site could be found.

Next we may briefly consider the problem of the dissemination of cultures. This is really the cardinal

* From the presidential address to Section H (Anthropology) of the British Association, entitled "The Place of Archæology as a Science, and Some Practical Problems in its Development", delivered at York on Sept. 2.

problem of archæology, irresistibly attractive, and for that very reason offering peculiar temptations to hasty and premature generalisation.

Now, the foundations of this particular study, in so far as they have been well and truly laid at all, have been laid not by archæology but by other sciences, those in fact which deal not with man himself but with the conditions necessary to his very existence. Geology, climatology, palæontology, palæobotany have been the instruments of that great progress in synthetic theory which I have pointed out as the special achievement of the last thirty or forty years. Those who have worked out the details and the stages of the Ice Age and the rainy periods have shown us that various parts of the world were uninhabitable for a long time. It is obvious, for example, that man cannot exist under a snowfield, so that it is useless to look for him north of lat. 50° until the Ice Age is well past.

Conversely, large areas which to the modern view seem impossible homes for man are shown to have been eminently suitable for the life of the palæolithic hunter. The Sahara and the Gobi desert in their present condition cannot maintain the life of man or beast; but the climatologist shows that there was a not very remote period when they were well-watered regions, covered with grass like the South African veldt, and teeming with large game. Thus he explains what otherwise might have remained an ambiguous problem for the archæologist, the finding of human implements of very early types in these apparently uninhabitable tracts.

The botanist next comes forward to tell us that the food plants on which a settled agricultural life depends can only be found in their wild state in certain closely defined areas. He also shows how changes of climate produce various types of afforestation which necessarily limit the movements and activities of a man who possesses only primitive tools.

But when the archæologist proceeds by purely archæological methods to fill in the details on a background of which the outlines are thus immutably drawn by the other sciences, he is confronted with innumerable difficulties of method, and the logic of his procedure is not always well studied. In the first place, we must necessarily rule out many types of reasoning which are so general and inconclusive that they can never carry any conviction. A little serious reflection must show that we necessarily know so little of the mental equipment of early man that it is often impossible to say what actions and habits are natural to all men as highly developed anthropoids, and what are so peculiar as to be specifically human and characteristic of one or another developed type of man.

That man should seek shelter from the elements is so obviously natural, and so like all other animals, that probably no one would argue that the living in caves or the construction of a primitive shelter, analogous to an animal's lair or a bird's nest, must presuppose any identity of race or origin. Or again, may not any animal pile up stones? And if so, at what exact stage does the piling up of stones become such a complex action that it can only be developed in one place? Suppose that a shelter of stones has to be roofed. Is the laying of slabs, one overlapping the other so as to form a corbel, so intricate a device that it might not be invented in many places simultaneously? It seems a very primitive process, even if it has been developed with great skill in certain countries.

It has sometimes been suggested that the discovery of the uses of burned clay, and consequently of baked pottery, may have been due to the accidental firing of a wattled hut. If so, it is difficult to maintain that the invention of pottery could only happen in one place, unless the use of fire was limited to one little spot on the earth.

These apparently elementary questions go to the root of the whole matter. Whatever answer an archæologist might give, he could not persuade by logical means any opponent who chose to disagree with him. He would be obliged, when driven into a corner, to say, "I am convinced" of this or that, but the conviction would express nothing more than his own temperament and psychology.

To apply logic at all, then, we need to find our material in highly specialised products or habits of man. In short, it is only possible to reason convincingly when manufactures or arts and crafts have reached a high point of intricacy. Let us take examples from flint-working, man's earliest craft. It seems fair to say that the use of natural flints, perhaps even of pre-Chellian or rostrocarinate and other forms which involve the minimum of workmanship, might arise independently among various types of almost simian man. But when it comes to elaborate chipping, and when this chipping produces implements of identical and highly specialised forms, then it is indeed logical to argue that this process and these forms could only have been invented once and only in one region. Chellian flints already seem to me to be so distinctly a product of a highly specialised intelligence, which might have taken a hundred other forms, that it must inevitably be inferred that a single type of man originated these artefacts, even though they are found distributed over an immense area.

Still more it might be supposed that when one more degree of elaboration has been added, by the use of so peculiar a technique as pressing off flakes as well as chipping, the logical inference was still stronger. If, further, this peculiar technique is combined with peculiar shapes, then the case seems to be almost irresistible. To accept this would entail some surprising consequences, linking, for example, the Badarian culture of earliest Egypt with the Solutrean of Europe and perhaps with other even remoter places. Yet it is certainly good reasoning. It is curiously significant, however, of the difficulty of arriving at any certain conclusions that just as we might be ready to accept this theory of the Solutrean, with all its far-reaching consequences, Menghin comes forward with the assertion that the Solutrean style is the natural and inevitable product of the juxtaposition of a core-working and a flake-working industry.

In contrast to the doubts and uncertainties which beset all reasoning based on the manufactures and

products of early man, it is a relief to turn to a field in which unquestionable logical certainty can be achieved. This is when we are able to study man's action in moving and displacing natural products. For when the natural distribution, as known to geologists, of rocks, ores, and other natural products is artificially changed, there can be no doubt that man has been at work. Thus, if a certain kind of flint is peculiar to Grand Pressigny in France and implements of that flint are found in Switzerland, there can be no doubt that Switzerland is trading with Pressigny. Similarly, if gold combined with antimony is known only to occur in Transylvania, it is a just, though a surprising, inference that the sceptre of a very early Egyptian king, living about 3000 B.C., which shows this unique combination of metals, is made of gold from Transylvania. To take a simple example from nearer home: if a number of stones in the circles of Stonehenge are of a type peculiar to Wales, they must have been transferred from Pembrokeshire to Salisbury Plain by man.

Raw materials, then, are better evidence than manufactures, especially in the earlier stages of man's life. When we are dealing with the works of man, logical processes of real value only begin to be applicable as handicrafts become more complicated and as the arts begin to emerge. Between art-styles, if we are sufficiently discriminating, it is possible to institute sound contrasts and comparisons. To take an extreme example, we should no doubt recognise a Greek statue even if it were found in West Africa. The hammer-axes of Troy and the Danube, the polygonal battle-axes so widely spread over southern Russia and northern Europe, the lunulæ of Irish gold, the decorated situlæ of Iron Age Italy, the painted vases of pre-Corinthian style, may stand as examples of highly specialised products which unquestionably denote commerce and reciprocal influence wherever they occur.

We have to be on our guard, however, against many cases in which the style is scarcely developed enough to be a convincing criterion, or in which the style has become so confused owing to cross influences that it gives an ambiguous answer. Most of all does this occur in the sphere of pottery. There is more bad reasoning in regard to pottery than in regard to any other part of our subject.

Especially in such early stages as the Neolithic and the Chalcolithic, there is the same danger of reasoning in too general terms that I have already pointed out in regard to primitive customs and habits. The smaller vessels used during the Neolithic stage are all imitations in clay of receptacles originally made in other materials. Goatskins, leather bags, gourds, and baskets are some of the natural predecessors of pots. It is only to be expected, therefore, that the clay imitations of these will be found far and wide among people who may have had no racial connexion or commercial intercourse of any kind. It is only occasionally that geographical conditions may intervene to prove that there is a real unity of culture underlying the superficial resemblances. There is, however, one happy instance of this. Gourds are indigenous in tropical and semi-tropical countries, but do not grow naturally in Europe. When, therefore, pots derived from gourd-forms are found in Moravia, it is a logical and necessary inference that the people who made them on the Danube came from a gourd-producing country like Asia Minor, or were in close commercial relation with it.

In this connexion, I should like to contrast two examples of reasoning, one of which has led to useful and fruitful results, while the other threatens to plunge us into confusion. All archæologists are agreed that the beakers which have such a wide distribution over Europe in the Bronze Age are derived from a single source, though they are not unanimous as to the centre of origin. This unification of a single system all over the west and north of Europe, including Great Britain, has greatly assisted the study of the Bronze Age in those regions. But contrast with this the attempts which are being made to unify the schools of painted pottery so as to make a chain from Chalcolithic Sicily to China. The dates are hopelessly incompatible over large sections of this immense area, the civilisations have few if any points in common, and yet we are invited to unify them on the sole basis of paint being used. It is even asserted in so many words that it is improbable that the idea of applying paint to pottery should arise independently in different centres. It might be too dogmatic to say that this is utterly illogical, but it can certainly be said that it is quite unconvincing. The discovery of paint is in itself easy and inevitable, and once this medium is known, it will naturally be used for anything and everything.

This leads me to make, in conclusion, the only suggestion that I think need be made in regard to the training of the young archæologists of the coming generation. I do not believe that early specialisation in archæological training would be wholesome—indeed, I think it would probably be rather harmful. As I mentally call over the roll of my most distinguished colleagues, some a little older and some a little younger than myself, I am struck with the remarkable diversity of their background and training. This diversity has probably been a real source of strength. That classical scholars, historians, anthropologists, geologists, lawyers, engineers, artists, and many other types of mind should focus from different angles on the same subjects has led to catholicity and breadth. For it is not so important that an archæologist should be an expert in one subject as that he should be widely and well educated.

With this premise once granted, I think that much time would be saved, and much efficiency would be added, if the student at the beginning of his archæological career were to superimpose a year or so of intensive technological training on his more general education. We all know the saying that a man does not really know about an object until he can make it. A technical training in primitive handicrafts such as pottery-making, flint-chipping, weaving, and the hammering, alloying, and casting of metals, would give him an insight which no mere reading or even handling of finished specimens can give.

Obituary

Sir Ronald Ross, K.C.B., K.C.M.G., F.R.S.

RONALD ROSS'S great discovery was made so long ago that it is difficult for anyone, unless he is nearer sixty than fifty years of age, to remember either the baffling mystery of malaria or the flood of light which his discovery threw not only on malaria, or even on tropical diseases generally, but also on all disease. His discovery disclosed conclusively a new method of the transmission of disease; and its practical importance was immediately recognised, as Great Britain was beginning to understand how vital it was to minimise the wastage of life involved in maintaining her Empire overseas.

Ross stated himself that it was about 1889 when he began to take his profession seriously, and he was specially attracted to the fever cases that mainly filled his hospital. As he had not heard of the work of Marchiafava, Celli, or Golgi, it is perhaps not surprising that he was unable to recognise the bodies described by Laveran. But a visit to London in 1894 brought him into contact with that other great figure in tropical medicine, Patrick Manson. Manson knew all that was to be known about malaria parasites at that time, and his penetrating mind had already decided that, in some way or another, the mosquito was the agent by which the disease passed from one man to another. Nor were his speculations merely the dreams of an idler, sitting in a comfortable arm-chair. Manson had worked in China and had there discovered two phenomena: the nocturnal appearance of the embryo of *Filaria bancrofti* in the blood of man, and the shedding of its sheath when the blood was cooled. He had wondered what all this meant. Had it any bearing on the life-history of the parasite? He had realised that this disease could not be spread by direct contact, and that some special mechanism was required to assist the parasite's escape from the human body. He rightly inferred that the mosquito was the most likely means by which that occurred. He reasoned that when the mosquito sucked blood from man, the parasites would be sucked in too, and that after living in the mosquito during its lifetime, they would escape on its death into water, from which they would again reach the body of man by ingestion.

Manson forthwith put his ideas to the test, for he was a man of action; and he saw things that convinced him that he was right. Men might tap their heads and suggest that Manson was mad in some of his ideas. I am sure he only smiled at that, for he had seen with his own eyes something that could have only one meaning, namely, that the parasites had found a congenial abode outside of man, and were growing in the mosquito. With this firmly fixed in his mind when he began to work on malaria in London, and when he saw certain strangely moving forms, he concluded that these were not due to the convulsions of a dying parasite, but were the beginnings of a new life cycle which would be spent partly in the mosquito, partly in water, and ultimately in man.

Manson told all these things to Ross; and it was decided that Ross should begin his investigation with the crescent form of parasite and try to follow the flagellum, that curious writhing thread which bursts from the crescent some time after blood has been drawn from man.

As it turned out, however, although the flagellum was the new phase of the parasite's life outside its human host, it was practically useless as a clue to the discovery of the secret. "Follow the flagellum" was Manson's advice; but the flagellum absolutely and utterly disappeared soon after it entered the mosquito's stomach, and it could be found neither in the stomach nor in any other tissue or organ of the insect. It is here that the genius of the younger man came to the aid of that of the older. For Ross had the perseverance that is required to make a great discovery, and he had the eye and mind to recognise the malaria parasite when it presented itself, strangely disguised, in the wall of the mosquito's stomach.

For nearly two years Ross hunted for the elusive thread. He dissected, he stated, more than a thousand mosquitoes, going through every possible tissue, and working out a technique that finally laid bare the parasite. What neither Ross nor Manson knew was that only a few species of anopheles carry malaria, and that in many parts of the tropics, India included, the number of the dangerous species is a very small percentage; indeed, in many places, only a fraction of one per cent of the total number of mosquitoes that buzz around and bite a man. But at last came the day when Ross had a new species of mosquito to feed. He bred it from a new kind of larva. He kept it in captivity, and he pictured in his notes the egg of the insect, which is clearly that of an anopheles. He fed it on a malarial patient; a few days later he dissected out the stomach of the mosquito by his own special technique, and there lay the malaria parasite—a tiny thing, but to the searcher's eye the thing he had sought so long and so patiently—indubitably the thing, for it had the fine grains of

pigment that the parasite in human blood contains. He had triumphed over the chief difficulties, and discovered the two unknown quantities, neither of which could have been found separately: first, where the parasite appeared in the tissues of the mosquito, and second, the kind of mosquito in which the parasite was found.

Now on the eve of complete triumph, an exasperating delay occurred. Ross was removed to a station in which there was no malaria; but thanks to Manson, he was put on to special research duty. He had learned how to keep mosquitoes alive for longer than Manson thought they lived, and he soon followed the development of the parasite through all its stages in the mosquito—the growing zygote in the stomach wall of the insect, the development of the sporozoites in the zygotes, the bursting of the zygote outwards, the spread of these sporozoites through the body juices of the mosquito, the presence of the salivary glands in the fore part of the body of the mosquito, the gathering of the sporozoites into the glands, the duct leading from the salivary glands direct to the proboscis of the mosquito, and the final and conclusive proof, the infection of healthy birds by the bite of mosquitoes containing these sporozoites in their salivary glands. Can we wonder that when Manson announced these discoveries to the Tropical Section of the British Medical Association at Edinburgh in 1898 they created a "profound sensation among the members", who stood and cheered?

To estimate the advance made by these discoveries, it is worth while for a moment to turn to what men knew of malaria when Ross began his work. Laveran had discovered the parasite of malaria. Malaria was no longer a vague mist floating over a swamp, that entered a man and caused chills and fevers, with a rhythm almost like the changes of the tide or the phases of the moon. The miasmic hypothesis of malaria was a fine conception; it explained better than any other all the facts of European malaria. It was, indeed, a very brilliant explanation of one of Nature's most cunningly hidden secrets. In Europe, it was true that malaria was a disease of low-lying swampy places, and that elevation gave immunity from the disease. But unfortunately, the explanation that fitted European malaria totally failed to explain it in other parts of the world. There, malaria was often virulent when there was only fast-running water and not a swamp within miles. Some of the most intensely malarial places were among the hills. Malaria occurred in deserts, as well as jungles; or in towns which were neither jungles, deserts, nor swamps.

Laveran gave precision to the conception of the disease, but did not show how it spread from man to man, although he had suggested that it might be carried by the mosquito. There were speculations and observations and experiments in abundance. Air, earth, and water were searched. Every excretion of man was examined: and claims were made that we now know were false. King in 1883 suggested that the mosquito picked up malaria in a swamp and infected man when it bit him, and gave nineteen reasons for this supposition, some of which were attractive and true within limits. Smith and Kilborne showed conclusively that Texas fever of cattle was caused by *Piroplasma bigeminum*, a blood parasite with some resemblance to the malaria parasite, and that it spread by means of the tick; but they failed to discover the parasites in the tick, and still less to demonstrate an elaborate life-history like that of human malaria in the mosquito. Manson thought the mosquito received the disease from man; that it died on water, and that man became infected either by drinking infected water or inhaling infected dust. Manson failed to prove that mosquitoes transmitted disease, because, even for so large a parasite as the *filaria*, his method and technique were at fault: method and technique being to science what organisation is to business, and at times even more essential.

In the long and arduous search, Ross had nothing to help him but his own indomitable perseverance and the genius to recognise what he saw. Had he not persevered and won through, the secret might have been a secret still. What a difference that would have made. If Manson could say that in some measure his only claim was he had discovered Ross, in like measure it might be said that Ross discovered to the world the genius of Manson. I can imagine the Goulstonian lecturer of 1998 referring to Manson and Ross, tracing their researches and discoveries, and the subsequent discoveries of the transmission of yellow fever, trypanosomiasis, tick fever, typhus fever, and other diseases by insects, and then asking his audience to think what a happy chance brought these two great men together.

Ross was happy in his great discovery. He was pleased at the honours he received. They were the highest the academic and scientific world could give. But he was never unduly elated, and he never forgot and never ceased to say that his work was not done for the sake of science, but for the sake of his fellow-men.

It was a bitter disappointment that the world made so little of the knowledge he gave it. With his far-seeing mind he realised that by his discovery the work of prevention was not ended,

but only begun. Even in the hour of triumph, when the shouts of victory might have distracted him, he wrote, in the very first paper he published after the discovery, that the way of progress was by further "experiment and research". It was, however, to be "experiment and research" on a scale larger, in time and space, than the medical profession had visualised, and the results have come in slowly for that reason; but solid progress has been made, and Ross's last birthday was brightened by good news from Africa about the development of the work to which he had devoted his genius and his life. Then clouds closed over one of the most active minds of his generation one of the foremost men of science of his time and on one of the great benefactors of mankind. He died at the Ross Institute, London, on Sept 16, 1932.

MALCOLM WATSON.

News and Views

Sir Ronald Ross

FOR many weeks the thoughts of scientific colleagues everywhere, as well as those of a large group of the lay public, have frequently turned to the bedside of Sir Ronald Ross where he was lying grievously ill. All who knew Sir Ronald personally cherished the hope that they might again be privileged to meet him, though in their minds they knew that such an event was unlikely. The parting came on Friday last, when he crossed the dark river into the land of silence. To few men have such brilliant and intellectual attributes been given, and none has had greater influence upon the comfort and welfare of the human race. The versatility of his genius was really remarkable. Not only was he the author of several mathematical works of high order, but his volumes of verse showed him to possess rich talents of poetic conception and expression. His scientific work is appropriately surveyed on p. 465 of this issue by Sir Malcolm Watson, director of tropical hygiene and principal of the Department of Malaria Control at the Ross Institute and Hospital for Tropical Diseases, where Sir Ronald Ross died. We are fortunate in being able to publish this appreciation from one who did so much to apply the results of Sir Ronald's investigations to anti-malarial measures in the Federated Malay States, Singapore, and elsewhere, and has been closely associated with him at the Ross Institute for several years.

SIR RONALD ROSS was born on May 13, 1857, at Almora, India, and after being educated at a private school, studied medicine at St. Bartholomew's Hospital, and entered the Indian Medical Service in 1881. His investigations on the life-history of the malarial parasite and the means of preventing malarial infection began with a clue indicated by Sir Patrick Manson. When Ross first attacked the problem in 1895, at Secunderabad in India, the circumstances entailed much difficulty and many delays. Here he opened up an investigation as to whether the malaria parasite, discovered by Laveran, passes part of its life-history within the body of a living insect. After more than two years of fruitless experiments, Ross discovered a stage of the human malaria parasite in the tissues of the mosquito, anopheles, which had been allowed to feed on the blood of a malarial patient. In 1898 he proceeded to work out in detail the life-history of the malarial parasite found in sparrows and larks in India. He traced the stages in development of this parasite from its inception into the stomach of the gnat, *Culex fatigans*, which feeds on the blood of these birds, to its passage back into their blood through the secretion of the poison gland of the insect. Thus he furnished conclusive experimental proof of the part played by the insect in propagating the infection. Ross was elected a fellow of the Royal Society in 1901, and in 1909 was awarded a Royal medal of the Society. He was awarded the Nobel prize in Physiology and Medicine in 1902; and national recognition of his work is represented by the honour of K.C.B. conferred upon him in 1911 and K.C.M.G. in 1918.

Egypt Exploration Society's Jubilee

BY exhibiting two relatively small collections of objects and manuscripts from the many thousands presented to the British Museum by the Egypt Exploration Society during the fifty years of its existence, the authorities of the Museum have fittingly marked the jubilee of the Society and once more reminded the public of the way in which the national collections have been enriched and the sum of the nation's wealth increased by the benefaction of private effort. Yet the objects which may be exhibited in the collections of a museum, however intrinsically valuable, priceless for their rarity, or instructive as a means of re-creating the history or the everyday life of a vanished civilisation, represent but a part of the achievement of an association of private individuals engaged in the common pursuit of the scientific exploration of the obscurer phases of the early history of mankind. A year or two ago, when the Society for the Promotion of Hellenic Studies celebrated its jubilee, its services to the cause of classical scholarship and the study of early Mediterranean culture were duly recognised. The Egypt Exploration Society, having in view its wider appeal, may justly claim an even greater achievement. With no assistance from public funds, it has brought to light, restored, and handed over to the Egyptian Government in trust for future generations some of the most impressive of the monuments of Egypt's past, such as the temples of Deir el-Bahari, the Osireion, and the tombs of Beni Hassan, while its most recent excavations in a humbler, but historically no less instructive, sphere at Amarna have revealed the material surroundings and dwelling-places of the general population of an Egyptian city.

THE activities of the Society in excavation have afforded an opportunity to many well known in the archæological world for the exercise of their skill. The list would be too long to recite, but the names of Petrie, Naville, Hall, Hogarth, Hunt, Grenfell, and Woolley in this connexion immediately leap to the mind. Their work has been recorded in the scholarly and beautifully illustrated publications of the Society. In the collections now specially exhibited in the Egyptian Galleries and the Manuscript Saloon of the British Museum may be seen some of the choicer relics excavated by them. These have been given to the Museum, it should be added, as the agreed method of disposal of the finds allotted for the share of the expenditure raised by subscription from private individuals. Over two score manuscripts, which include the priceless "Sayings of Jesus", new poems by Sappho and Bacchylides, and the text of Pindar's "Pæans", are shown. Among the more striking archæological exhibits are the polychrome glass fish from 'Amarna and the sandstone sphinx inscribed with the famous pictographic script of Sinai, both of which have attracted much attention from the public, the diminutive gold statuette of Re, and the silver shrine from Daphnæ. With a number of exhibits of decorated glazed ware discovered at Amarna in the last two or three seasons' work is the unique Eighteenth Dynasty ivory *ushabti* from that site, whence also comes, among the finds of the season just past, the remarkably fine engraving of a young king's head on limestone, while the limestone head of a bald-headed old man, shown near by, comes from Deir el-Bahari. The relics from the recently discovered Buchæum, the temple of the Buchis bull cult, are here on exhibition for the first time. The larger objects and statues in the Gallery, for which the Museum is indebted to the Society, have been specially labelled.

Old and New Pharmacy

A WRITER in the Sunday *Observer* recently deplored the passing of the old-time English pharmacy with its window display of stoppered carboys of coloured water and its opal and gilded drug-jars. The loss of these emblems coincides with a change in the character of the pharmacist's occupation. The centralisation of manufacture tends more and more to convert him into a distributor of compounded medicines, in place of the skilled technician who made his own preparations out of crude drugs; but it must not be forgotten that he must now know a great deal more, about more complex drugs, than the old-time pharmacist. Side by side with this change there has grown up a demand on the part of pharmaceutical and fine chemical manufacturers for a new kind of pharmacist, whose knowledge is varied enough to enable him to deal with the new developments in therapeutics to which chemists, pharmacologists, and physiologists are constantly contributing. Much the same type of pharmacist is required by the great hospitals, which in these days often undertake the manufacture of pharmaceutical products on a considerable scale, for the use of their patients. To meet these new demands pharmaceutical education in Great Britain has been and is still being remodelled, and if any justification is needed for the changes the Pharmaceutical Society is making in this direction, it will be found in the new "British Pharmacopœia", to be published next month. The advance notices of this work, which have appeared in the technical press, indicate that it will make greatly increased demands on the knowledge and skill of the pharmacist, even where he is only concerned with the care and distribution of the vast number of products used in modern medicine.

British Pharmaceutical Conference

IN these circumstances it was peculiarly fitting that the chairmanship of the annual meeting of the British Pharmaceutical Conference at Aberdeen should have fallen this year to Mr. Herbert Skinner, the veteran pharmacist of the Great Northern Hospital and a former president of the Pharmaceutical Society of Great Britain. In his opening address, Mr. Skinner deplored the tendency, which exists even among medical men, to regard the hospital pharmacist as merely a dispenser of medicines, and out of his own rich experience drew an interesting picture of the duties and responsibilities attached to such a position, in the course of which he insisted on the necessity of maintaining a laboratory in every pharmacy, if the pharmacist is not to lapse into a mere distributor. The number of papers contributed to the Science Section of the Conference was twenty-nine, which is stated to be a record. It is perhaps to be expected in a year which sees the advent of a new "Pharmacopœia" that these papers should be largely concerned with methods of analysis of drugs. The importance of this kind of work is obvious, since upon it depends control of the purity and strength of drugs, but it is to be hoped that at future Conferences there will be more papers of the type contributed by Dr. Linnell and his colleagues on the synthesis of pressor substances and local anæsthetics, since these imply the development of interest in the synthesis of new drugs in Great Britain.

New Zealand Earthquake of Sept. 16

SINCE Feb. 3, 1931, the strongest earthquake in the Hawke's Bay district is that which occurred at 1·30 A.M. on Sept. 16. In 1931 the principal damage was confined to Napier, Hastings, Waipawa, and other places lying within an elongated area about fifty miles in length and directed north-north-east. The earthquake of Sept. 16, though much less intense and unaccompanied by loss of life, was strong enough to cause slight damage, such as the partial collapse of some houses at Wairoa and Gisborne, to the north of Hawke's Bay. These places lie nearly along the continuation of the areas mainly shaken in 1931, but the centres of the two meizoseismal areas are separated by about eighty miles. The point of chief interest about the recent earthquake is the continual migration of the focus in the north-north-easterly direction from 1855 until 1931 and again until Sept. 16 last.

Henry Cavendish

WITH reference to a paragraph which appeared in these columns in the issue of NATURE for Aug. 6 (p. 198),

in which the ascription of the title 'Honourable' to Henry Cavendish was described as a persistent delusion, Dr. E. J. Holmyard writes: "This stricture appears to be based upon a misapprehension. It is only within the last hundred years that the title 'Honourable' has been conventionally limited to the children of peers below the rank of marquis, and that it was commonly given to Cavendish is shown both by the admission register of Peterhouse (where he is described as 'Honorabilis Henricus Cavendish') and by the fact that Wilson's 'Life' (London, 1851), written when many of Cavendish's contemporaries were still living, employs the title without comment." Dr. Holmyard, however, will find that the definition of the term given in early reference books (for example, "Encyclopædia Britannica", 3rd ed., 1797) is exactly the same as the one in force to-day, and allows no excuse for the ascription to Cavendish. Cavendish's father, Lord Charles Cavendish, was not a peer, and however loosely the term might have been used and accepted in those days, it seems quite clear that Henry Cavendish had no right to it, and that it was incorrectly applied to his name and has been as incorrectly accepted without question until now.

League of Nations Intellectual Co-operation Organisation

THE International Institute of Intellectual Co-operation (2 Rue de Montpensier, Paris I) has just published the first number of a new monthly *Information Bulletin*, as the official organ of the League of Nations Intellectual Co-operation Organisation, which comprises a committee of the League with its secretariat at Geneva, the Institute in Paris, committees of experts, and national committees. It is a counterpart in English of the Institute's *Bulletin de la Coopération intellectuelle*, most of the contents of which will be summarised in it. This first number contains a review by the director of the Institute of recent developments in this field, special articles on the reorganisation of education in China and on "Moral Disarmament", a summary of the month, reports of meetings held under the auspices of the League's Organisation, and notices of forthcoming congresses. A foreword by Sir Eric Drummond commends it to the notice of all those who are interested in the promotion of international co-operation in art, education, science, and scholarship and believe that its progressive development is an essential condition for the gradual realisation of the principles for which the League of Nations stands. The annual subscription is 10 shillings or 2 dollars: single copies, 1 shilling or 20 cents.

Soil Physics in Relation to Meteorology

DR. B. A. KEEN, of the Rothamsted Experimental Station, discussed "Soil Physics in Relation to Meteorology" at the G. J. Symonds Memorial Lecture for 1932 of the Royal Meteorological Society (*Q. J. Roy. Met. Soc.*, July). This new branch of physics has made it necessary to discard a number of generally accepted explanations of agricultural and horticultural matters connected with the soil. Russian work on soil classification has, for example, led to the recognition of certain soil groups as a basis for a survey of the soils of the whole world, and it is found that the type of soil formed in any place is dependent not so much upon the geology of the neighbourhood as upon certain meteorological factors, especially temperature and rainfall. Analysis of vertical sections of the soil, or soil 'profiles', shows unmistakably that the amount of percolation of rain water decides whether certain alkaline salts derived from the weathering of rocks shall be washed downwards or not, and it is because of their effect upon percolation that these two meteorological factors are so important. As an offset to this case of underestimation of meteorological influence, Dr. Keen cites a case of overestimation, the subject being the aeration of the soil. The point that had to be explained was how it comes about that the composition of the soil atmosphere is so nearly the same as that of ordinary air, in spite of the fact that most biological activity in the soil tends to absorb oxygen and evolve carbon dioxide. A critical examination of the different processes leading to gaseous exchange between the soil and the atmosphere points to ordinary gaseous diffusion as the principal agent of exchange, meteorological processes being too slow. The rate of diffusion, moreover, is dependent upon total pore space rather than upon the size of individual pores, which would appear to dispose of the idea that 'heavy' soils—those with the smallest particles—are necessarily the most badly aerated. Another important point made in the lecture is that water is not conveyed to the surface of the ground by capillary action from nearly such great depths as had at one time been supposed, from which it follows that the good effect of a surface mulch of loose soil or other material is often unconnected with the reduction of evaporation from the surface.

The Newcomen Society

THE Newcomen Society for the study of the history of engineering and technology has just published its tenth volume of *Transactions*, containing the papers read during the year 1929–30, various notes and contributions, and a subject list of books and pamphlets relating to the history of technology, 1931–32. To mark the completion of ten years' labour, the Council has included in this volume a complete index to the whole of the *Transactions* and also an index to the various bibliographies. Both these indexes should prove of great use. As usual, the papers and notes cover a very wide field, ranging from ancient civilisations to the first steam engine in America and bell-founding; while the printing and illustrations leave little to be desired. The Society's financial position is sound, and the membership has increased slightly; more than a quarter of the members reside in the United States. Each year the Society holds a short summer meeting in the provinces, and it never fails in bringing to light the existence of historical industrial sites or directing attention to the industrial history of the district in which it meets. From time to time it has either taken the initiative or co-operated in the commemoration of the centenaries of

eminent engineers and inventors, and we understand it has already taken steps which should ensure the proper recognition of the centenary of the great Cornish engineer Richard Trevithick, who died in 1833. Trevithick died in poverty at Dartford and lies in an unknown grave, but in 1883, through the action of the Institution of Civil Engineers, a window in his memory was erected in Westminster Abbey. He was one of the most gifted inventors who ever lived, while as an engineer he was the pioneer of the high-pressure steam engine, and this at a time when the authority of Watt, who would have nothing to do with high pressures, was almost world-wide.

An Empire Museum Survey

Amongst many topics dealt with by Sir Henry Miers in his fourth presidential address to the Museums Association was that of an Empire Museum Survey. A few years ago the possibility of so great a venture would have occurred to no one; now the Survey itself is far advanced towards accomplishment, thanks to the initiative and energy of Sir Henry Miers himself. It began with the Carnegie United Kingdom Trust survey of the museums of the British Isles; it was continued with rapidity when the Carnegie Corporation of New York, in addition to all it is doing for the United States, expressed its willingness to expend certain funds allocated for expenditure within the British Empire (exclusive of the British Isles) upon such a scheme. In 1931, Sir Henry Miers and Mr. Markham visited 121 museums and galleries in Canada; early this year they visited all the museums they could discover in the Union of South Africa and in Rhodesia, as well as many others encountered on the return journey by Khartoum, Cairo, and Port Said. This year also a survey of museums in British possessions in the Mediterranean Sea was carried out by Alderman Squire and Mr. Herdman. So that in a year, from June 1931 until June 1932, two-thirds of the Empire Survey has been completed; and now there remain only to be tackled the Commonwealth of Australia, Tasmania, New Zealand, the West Indies, and a few almost inaccessible places like the Falkland Islands.

Mississippi Floods

The disastrous floods in the Mississippi basin in the spring of 1927 have led to various suggestions for preventing their recurrence. These are critically examined by M. O. Messerly in a paper entitled "Les Travaux de defénse du Mississippi" in *Matériaux pour l'etude des calamités*, No. 3, année 1931 (1932). Several of the proposals would probably lead to effective defence, but are not feasible on the score of cost. The construction of reservoirs on the tributary streams would be useful but very expensive. In industrial districts, however, such reservoirs would have a local use, in addition to their protective value. Setting back the embankments along the lower reaches, if done on a large enough scale, would help considerably, but is scarcely practicable. Dredging of the bed would be effective, but only if continuous and on a very large scale. Afforestation might help in checking the flow of rainfall to the rivers, but even vast schemes might afford only small relief. In any case, the effect would not be felt for a generation or more. The most practical measures seem to be the raising and strengthening of the embankments at certain places, the construction of new drainage channels parallel with the main stream, and the straightening of the river in places to facilitate the flow of water.

Duck Decoy Ponds in Europe

Science Service (Washington, D.C.) publishes a Berlin message concerning the slaughter of migratory ducks by decoy ponds in Europe. In Germany there are at present eleven decoys, with an average annual catch of 40,000 ducks; in Denmark two, with an average of 12,000; in Belgium four, average not stated. England is said to have twenty-one, capturing about 600 ducks; and Holland to have the greatest number of decoys, 145, having an average yearly catch of 300,000 ducks—a number until now suppressed in the interest of the Dutch canning industry, which has built up a profitable export trade upon the proceeds of the decoys. The finding of ringed birds shows that the ducks caught in Holland come largely from Scandinavia and Finland, and the fear is that the supply will eventually fail under this serious annual drainage. The open season lasts from July 27 until Feb. 14, or even March 13, and a shortening of this period would have a good effect, but it is said that the Dutch Government is unwilling to interfere with a profitable home industry. Nevertheless, an effort will be made, at the International Conference, to have the open season reduced to a period from Sept. 15 until Jan. 31.

Bibliography of Newcastle-upon-Tyne Local Records

As all interested in bibliographical matters no doubt know, Newcastle-upon-Tyne possesses an excellent public library, rich not only in the books generally found in such institutions, but also particularly in works of local interest. Having regard to the fact that Newcastle-upon-Tyne and the district of which it is the centre have taken such a prominent part in the invention and the development of technical methods and appliances of great industrial importance, it is obvious that these records of local doings necessarily appeal to a far wider public, and the librarian, Mr. Basil Anderton, has done well in publishing a "Catalogue of Local Records". The catalogue falls into two main divisions, namely, an author list and a subject list, together with certain appendixes which are perhaps of more strictly local interest. The subject list will probably be the one that will be more generally consulted, and it contains material of the greatest value, especially to the historian of matters of technological or sociological import. It need scarcely be said that in a coal-mining centre like Newcastle-upon-Tyne, maps of the coal mines and royalties of the surrounding district play an important part, and give information of the utmost value to students of the development of the coal-mining industry. The catalogue appears to be very well executed, is well printed and published, and will form a valuable and useful addition to British bibliography.

Progress of the Ordnance Survey

The Report on the Progress of the Ordnance Survey for the year ending March 31, 1932, directs attention to the steadily increasing sale of small-scale maps, particularly the one-inch scale. This is no doubt due

to their increased use by walkers and cyclists. The fourth revision of the one-inch maps is making progress in the south of England, and Sheet 144 has been published in the new style. On the other hand, the revision of the six-inch sheets has fallen into arrears, which it is hoped will shortly be overtaken. Owing to lack of adequate staff, it has become necessary to restrict revision of the 1/2500 scale plans to those sheets which are found to be very considerably out of date owing to development of the ground. By this restriction it is hoped to overtake the more important arrears of work in areas of recent urban growth. Key maps of Great Britain attached to the Report show that in the greater part of Scotland and Wales and much of England the last revision of the 1/2500 and six-inch scales was more than twenty years ago.

Manufacture of Electric Railway Equipment

THE surburban services of the Danish State Railway around Copenhagen are to be converted to electric working on the high-pressure direct current system at 1500 volts. We learn from the *English Electric Journal* for July that the contract for 42 motor coaches and 21 trailer coaches has been awarded to the English Electric Company. There are now 'English Electric' equipments operating railways in seventeen different countries of the world. The Danish State Railway is the fifty-sixth railway to be electrified with the Company's material. The first high-voltage direct current electric railway operating in the world was the Bury-Holcombe Brook route of the Lancashire and Yorkshire Railway. In 1913, the English Electric Company developed the motors and control gear used on this line, which operated on 3600 volts. Few companies have had such world-wide experience in making electric railway equipment of all kinds.

Baltic Geographical Studies

THE report of the twenty-fourth meeting of German geographers held at Danzig on May 26–28, 1931, has been published as a volume (Verhandlungen und wissenschaftliche Abhandlungen des 24 Deutschen Geographentages, Breslau), which contains, in addition to the proceedings of the conference, a number of valuable papers. These cover a wide range of topics, but perhaps the most striking is a series on Baltic geography, including a paper by Prof. G. Braun on the oscillations of level of north-western Europe and the development of the Baltic from glacial times. A tabulated chronology of changes in the area makes an interesting study. Prof. B. Schulz writes on the waters of the Baltic, and Dr. W. Quade contributes a long study on the evolution of the port of Danzig in relation to the changes in the mouths of the Vistula. This paper is illustrated by a number of old charts.

The Imperial Economic Committee

THE twenty-sixth Report of the Imperial Economic Committee consists of a review of its constitution and work, and traces the development of its terms of reference. Suggested at the Imperial Economic Conference of 1923, the Committee was brought into being in 1925 with very restricted terms of reference that dealt only with the marketing of Empire food products in Great Britain. This led to the institution of the Empire Marketing Board in 1926, the year in which the Imperial Conference widened the work of the Committee to include the consideration of raw materials of manufacture as well as foodstuffs, and also industries and trades. The Conference of 1930 laid stress on the survey of mineral resources, and entrusted the Committee with the study of various aspects of Imperial co-operation. Its numerous reports on various products and materials are of considerable scientific value.

Announcements

THE opening meeting of the eighth session of the Electroplaters' and Depositors' Technical Society will be held on Sept. 28, at Lyons' Angel Café, Islington, N.1, when a discussion will be held on "The Possibilities of Standardising Electrodeposits".

THE Institute of Transport has made the following premium awards for the session 1931–32: Institute Triennial Gold Medal to Sir Lynden Macassey; Railway (Operating) Gold Medal to H. H. Mauldin; Railway (Engineering) Gold Medal to Sir Harold Hartley; Road Transport (Passenger) Gold Medal to Horace M. Wyatt; Water Transport (Canal) Gold Medal to A. J. Pearson; and Institute Graduate Silver Medal to J. M. Powell.

ORNITHOLOGISTS will be interested in Messrs. Wheldon and Wesley's new catalogue of ornithological works, which includes 2039 items. The collection is notable for the large number of important books it contains, and readers unfamiliar with the demand for such works may be surprised to learn that the seven volumes of Lilford's "Birds of the British Isles" are priced at £32, Dresser's "History of the Birds of Europe" at £48, Gould's "Birds of Europe" at £70, and his "Birds of Asia" at £175.

THE following scholarships have been awarded by the Institution of Electrical Engineers for 1932: Ferranti scholarship to C. D. J. Statham (University of Sheffield); Duddell scholarship to P. J. Rattue (Staveley Grammar School); Silvanus Thompson scholarship to W. E. Arnold (London Midland and Scottish Railway Co.); Swan memorial scholarship to G. N. Davison (Sunderland Technical College); David Hughes scholarship to R. G. Armstrong (University College, London); Salomons scholarship to J. S. Wright (King's College, London); War Thanksgiving education and research fund (No. 1) to G. J. Scoles (University College, London) and T. H. Walker (University of Sheffield); Thorrowgood scholarship to B. O. Banks (Metropolitan Railway).

MEMBERS of the staff of the Rothamsted Experimental Station are offering to give, during the forthcoming winter, a few lectures on the experimental work of the Station, to chambers of agriculture and horticulture, farmers' clubs, farm workers' associations, agricultural societies, etc. No fee will be charged for such lectures, but the association engaging the lecturer must defray his expenses. The subjects offered include manures, soil micro-organisms, agricultural botany, agricultural chemistry, soil physics, entomology, and mycology. Further particulars can be obtained from the Secretary, Rothamsted Experimental Station, Harpenden, Herts.

Letters to the Editor

[The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, nor to correspond with the writers of, rejected manuscripts intended for this or any other part of Nature. *No notice is taken of anonymous communications.]*

Polarisation of Wireless Echoes

We were much interested in Mr. T. L. Eckersley's description[1] of a method of demonstrating the polarisation of wireless echoes, but surprised to find that some of the results he mentions appear both contradictory to the magneto-ionic theory and also to those obtained when other comparable methods of polarisation delineation are employed in the same connexion. Soon after Mr. Builder and one of us described the occurrence of regular echo-doublets and suggested that they were composed of the two oppositely polarised magneto-ionic components, various methods of demonstrating the correctness of this hypothesis were devised by members of the group of workers associated with the Radio Research Board. Some months ago Mr. R. A. Watson Watt and one of us, at the Radio Research Station, Slough, and Mr. E. L. C. White and the other, at the Cavendish Laboratory, Cambridge, independently and simultaneously developed apparatus for demonstrating the different polarisations of the echo-doublet components. The Cambridge apparatus is similar in principle to that of Mr. Eckersley, but is somewhat simpler to construct and to adjust.

In the apparatus used at Slough (and also at Radio Research Station, Tromsö) a radio-polarimeter is used in which the polarisation of the separate components is delineated on a cathode-ray screen. This method possesses the advantage that the complete polarisation specification, circular or elliptical, right-handed or left-handed, is shown by the oscillographic trace, and it is not necessary to assume, *a priori*, as with Mr. Eckersley's apparatus, that the components are circularly, and not elliptically, polarised. (A brief description of this apparatus, together with a statement that the echo-doublet components had been shown to be of opposite polarisation, appeared early in July last.[2])

With both these methods, and also with still another in use at King's College, London, it has been demonstrated that the components of a doublet echo are oppositely polarised in sense, the usual but not quite invariable result being that, when simple splitting is in evidence, the component of lesser delay is of right-handed sense and the component of greater delay left-handed. (We here use the same convention as Mr. Eckersley and view the polarisation looking in the direction of propagation of the waves.) Many observations on split echoes have been made using these methods at Cambridge, the Radio Research Station, Slough, and King's College, London, and a full account of them will, we hope, soon be published. The results obtained by the different methods are in close agreement, and also fit in with those of previous polarisation determinations made on longer wavelengths using the frequency-change method.

In connexion with the daytime absorption of the waves, we find ourselves in disagreement with Mr. Eckersley both as to the experimental results and as to the interpretation of the magneto-ionic theory. Experimentally we have found that, with wavelengths such as Mr. Eckersley mentions, while both components may be present, the left-handed one is more frequently that of greater intensity. The presence of both components is in agreement with the observations of Krüger and Plendl,[3] who found that at vertical incidence waves of 53 metres were returned from the ionosphere plane polarised with a rotating plane of polarisation. This would be the result of the presence of two circularly polarised components with a varying phase difference. Our deduction from the magneto-ionic theory is just the reverse of Mr. Eckersley's, for we find that the theory suggests that it is the right-handed component which suffers the greater absorption.

We cannot understand the contradiction between our results and those of Mr. Eckersley, and look forward to the publication of a full account of his theory and experiments so that we can trace exactly where the difference lies.

Spectrum of Cosmic Radiation

Cosmic radiation forms a whole series of lines or bands in its spectrum, as can be established by measuring its absorption coefficient. The most penetrating of its constituents, having energy of about 3700 million volts, originates, according to Sir James Jeans, in the annihilation of an α-particle and its two neutralising electrons,[1] while the next softer constituent, of energy about 950 million volts, is formed by the annihilation of one proton and its neutralising electron. In both these cases, as generally accepted, one can scarcely suggest any other interpretation. The interpretation, however, of the softer constituents by the formation of helium and higher atoms from 'metastable clusters' consisting of protons and electrons, as suggested by Prof. R. A. Millikan,[2] has supplemented the first assumption of the origin of cosmic radiation:

$$\text{Proton} + \text{Electron} = h\nu,$$

made by Sir James Jeans, which seemed unable to give more than one line and did not indicate any logical or numerical connexion between the energy value of the proton-annihilation constituent and those of softer ones.

The object of this note is to point out a curious regularity which seems to occur in the energy values of the constituents of cosmic radiation. If we divide the annihilation quantum of the proton $h\nu \cong 950$ million volts by $n(n+1)$, where $n = 0, 1, 2, 3, 4, \ldots$, we get the values tabulated below (expressed in millions) together with those observed in cosmic radiation:

n	0	1	2	3	4	5	6	7
$h\nu$ calcul.	950	475	160	80	48	32	22	17
$h\nu$ observed	~950	~450	~180	~100	?	~30	(22·5)	~15

The observed values given under $n = 5$ and $n = 7$ are the limits of the 'soft band' as established by Prof. Millikan by measuring its penetrating power in comparison with that of γ-rays of thorium C'', the value 22·5 million volts being their average.

If this is not a pure accident—and one can scarcely believe it is—it must appear very surprising that an equation of the form

$$h\nu = \frac{h\nu_{\text{annih.}}}{n(n+1)}$$

succeeds so well in reproducing the spectrum of cosmic radiation in terms of the energy value of annihilation

of the proton-electron system. For, it is the very form deduced by Schrödinger for the quantum levels of the rotator with free axis.

Cystine and Wool Production

IN 1928 Marston and Brailsford Robertson emphasised the importance of cystine in the biology of the sheep.[1] They considered that since a typical fodder protein such as that of lucerne contains 0·93 per cent of cystine and the keratin of wool fibre contains 13·1 per cent, cystine might well be a limiting factor in the production of wool. Three assumptions were made by them, namely, that the cystine content of pasture lies within certain limits, that cystine cannot be synthesised in the animal body, and that the cystine of wool fibre is relatively constant.

As regards the first point, Evans[2] and Aitken[3] have shown that the cystine of pasture grass is of such a small order, about 0·01 per cent, by weight, of dry matter, that, as pointed out by Rimington and Bekker,[4] the amount of cystine present in the grass consumed by a sheep cannot be made to account for the amount of cystine present in the fleece. The argument of Rimington and Bekker depends upon the correctness of the figures of cystine analysis of grass, which, as pointed out by Marston,[5] is one of extreme difficulty and complexity, and it is probable that the figures must at present be accepted with caution.

The results of a recent experiment performed in collaboration between the Rowett Institute and the Wool Industries Research Association, Leeds, which are to be published fully at a later date, throw light on the matter at a new angle. During the course of the experiment, a group of twenty sheep received 503 lb. of digestible protein. The crude weight of the wool produced during the same period was 72 lb. Allowance has to be made for grease, impurities, and moisture content. Thus:

	lb.	lb.
Crude weight of wool	..	72
Grease and impurities . . .	15·5	
Moisture content . . .	10·4	
		25·9
Estimated weight of clean dry wool ..		46·1

The weight of the clean dry wool, therefore, corresponds to 9·2 per cent of the weight of the digestible protein fed. Accepting the figure of 13 per cent as an approximate value for the cystine content of wool, the 46·1 lb. of clean dry wool would contain 6·0 lb. of cystine, corresponding to 1·19 per cent of the weight of digestible protein food. Making the generous allowance of 40 per cent of the ingested cystine retained as wool, the cystine content of the protein fed would correspond to the figure of 2·88 per cent given for blood albumin by Brailsford Robertson and Marston.[1] The proteins actually fed were those of turnips, oat straw, maize, bran, oats, and distiller's dried grains. Since the cystine content of such vegetable proteins is much lower than that of blood albumin, it is difficult to avoid the conclusion that some synthesis of cystine took place.

Finally, in a series of important papers, King, Barritt, and their colleagues at Leeds have shown quite conclusively that the cystine content of wool fibre is not constant, but that it fluctuates within fairly wide limits.

It follows that the evidence available in contradiction to the hypothesis of Marston and Brailsford Robertson suggests that the cystine content of pasture is so low that it cannot be conceived as being a possible limiting factor in wool production, that synthesis of cystine very possibly occurs in the sheep, and that the cystine content of wool fibre is not constant.

The experimental evidence cited by Marston in a recent communication[5] is unsatisfactory. An experiment by Lines is quoted in which casein was contrasted with yeast (containing 3·5 gm. cystine a day) as a source of nitrogen superimposed on a protein-deficient basal diet. The yeast gave very much better results, but the vitamin, mineral, and other factors present in yeast were apparently ignored, and were certainly not controlled.

In a field experiment in Central Queensland, blood meal (containing 2·7 per cent cystine) was fed *ad lib.* to ewes and lambs, the maximum intake of 6 oz. a head a week being reached under drought conditions. Unfortunately, the experiment was not controlled, since a cystine-poor concentrate of equal caloric value was not fed to the control group. It is therefore impossible to say how much, if any, of the beneficial effect was due to cystine or even to protein.

The bulk of the evidence is thus in favour of the synthesis of cystine within the sheep, and the question of the possible mode of synthesis arises. Rimington and Bekker suggest the decomposition of symbiotic intestinal bacteria as the source. On this hypothesis, sheep reared from birth on sterilised foodstuffs (suitably supplemented with vitamins) should grow little, if any, wool. It is therefore a hypothesis capable of critical test. The fact that wool growth is at its maximum before the lamb's rumen has fully developed is against this view.

It seems to us possible that cystine is formed during keratinisation, and that cystine synthesis is a function of the wool follicle itself. The amount of cystine produced in a fleece would then depend upon the number and activity of the wool follicles, and not upon the cystine content of the food or the bacterial population of the intestines. It appears to us that this hypothesis accords more closely with the great diversity of weight of fleece grown by different breeds under the same environmental conditions.

Diffraction of X-Rays by Liquid Metals

WHEN a beam of monochromatic X-rays is passed through a liquid, the intensity of scattered radiation does not, in general, fall off uniformly with scattering angle. One or more regions of maximum intensity are usually observed, and these may appear as bands or diffuse rings on a photographic plate placed to receive the rays. These facts are well known. Nevertheless, it is probably true to say that no completely satisfying explanation of such effects has yet been produced. One of the most attractive proposals has been put forward by G. W. Stewart in a series of recent papers.[1] Stewart suggests that temporary groupings of considerable numbers of atoms or molecules in the liquid would account for the observed

diffraction effects. This view is somewhat strengthened by the observation that the maxima for the liquid state are frequently in positions very similar to those of the strongest maxima for the solid material. It therefore appears that the units in the liquid are probably trying to group themselves according to their customary positions below the melting point.

The testing of any quantitative theory of the liquid state will probably be much simplified if results on simple substances are available. With this end in view, we have recently carried out X-ray diffraction experiments on several liquid metals. So far, liquid sodium, potassium, rubidium, and cæsium have been investigated, and work on lithium, lead, zinc, cadmium, bismuth, and other elements is proceeding. Sodium, potassium, rubidium, and cæsium are of the body-centred cubic type in the solid state, and the liquids, at temperatures not very far removed from the melting point, each diffract the X-rays in one main direction, so that a single narrow band is observed. Fig. 1, showing the ring for rubidium, gives

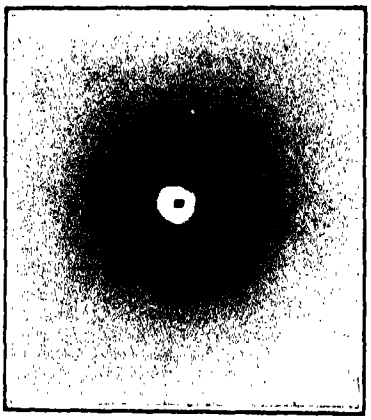

FIG. 1.—X-ray diffraction pattern for liquid rubidium. Copper $K\alpha$ radiation. Spacing of band, 4·00 A.

some idea of the rather surprising sharpness of definition obtained with all four liquids. The accompanying table gives approximate spacings of the bands. The metals were in each case distilled into exceedingly fine glass capillaries, and the melting carried out by means of an external heating coil.

Element.	Approximate Spacing in A. of Band due to Liquid.	Approximate Width of Band in Degrees at Half Intensity.	Spacing of (110) Plane for Solid in A.
Sodium .	3·01	6° 0′	3·04
Potassium	3·87	— *	3·68
Rubidium	4·09	4° 50′	3·97
Cæsium .	4·51	9° 30′	4·28

* Microphotometer records of our films for liquid potassium are not yet available.

It may be noted that in each case the spacing of the liquid band is approximately the same as the spacing of the strongest line of the corresponding solid. Work is now proceeding on the correct interpretation of these results, a full discussion of which we hope to publish elsewhere.

Electrochemical Periodicities

DR. J. A. V. BUTLER and G. Armstrong[1] and Dr. E. S. Hedges[2] have published some very interesting observations on periodicities in electrolitic cells. I have made similar observations in a cell with 25 per cent sulphuric acid as electrolyte and a copper anode. The e.m.f. and resistance of the circuit being constant, under certain conditions the current through the cell assumes values from a few milliamperes to a fraction of a milliampere alternatively. The time of the alternations is variable, under different conditions, from about one to ten seconds.

This phenomenon lasts from several minutes to one hour or more, changing gradually. It is essential for the production of these oscillations that the ratio between e.m.f. and circuit resistance should have a certain value, corresponding to a critical value of the current density, approximately 43 ma./cm.^{2}

This phenomenon is caused by periodical variations of the cell resistance,[3] due to the alternative formation and destruction of a thin insulating layer on the anode. This layer is analogous to that responsible for the passivity of metallic electrodes.

Thermochemistry and the Periodic Table

(ENERGY OF TRANSFER OF ELECTRONS ON OXIDATION)

SINCE the formation of chemical compounds depends on rearrangements among the electrons of the outer shells of the atoms concerned, it may well become the aim of thermochemists to connect changes of energy with the corresponding change in the arrangement of those electrons.

In my endeavours to develop the subject on these lines, I have been handicapped by scarcity of data. The energy of formation of the direct linking of oxygen to a number of elements has, however, now been obtained by C. R. Bailey[1] from the band spectra (in the infra-red) of a number of non-polar compounds examined by him at University College, London.

In the accompanying table these energies are correlated with the covalencies of the elements concerned:

Element.	Energy of Linkage with Oxygen (per gm.-atom of element). Kilo-cal.	Covalency of Element.	Column 2. / Column 3. Kilo-cal.
First Periodic Series			
Hydrogen . .	110	1	110
Second Periodic Series			
Carbon . . .	237	4	59·3
Nitrogen . .	171	3	57·0 Mean 58·6
Oxygen . .	118	2	59·0
Fluorine . .	59	1	59·0
Third Periodic Series			
Silicon . .	180 (?)	4	45·0 (?)
Phosphorus . .	148	3	49·3
Sulphur . .	101	2	50·5 Mean 49·9
Chlorine . .	50	1	50·0

In column 2 of the table, the energy of formation of the linkage H-O, as in water vapour, has been added to the series given graphically by Bailey.[1]

These energies of formation are seen to be a periodic function of the atomic number, being large for the early members of a series and decreasing steadily until

a minimum is reached for the last member of the series.

Such periodicity in a physical quantity is usual. What are not usual, however, are the regularities found in column 4. These call for special comment, and may be explained on the following lines:

(1) The covalency of the element is a measure of the number of electrons transferred from the oxygen in order to produce a stable shell.

(2) The energy of linkage divided by the covalency, therefore, represents that portion of the energy of the linkage which is directly associated with the transfer of one electron from the oxygen.

The energy per electron, estimated in this way, is seen in column 4 to have approximately the same value, 59 kcal., for the linkage of oxygen with each of the several atoms of the second series of the periodic table, that is, with atoms consisting of a nucleus and one shell of electrons. Lower values are obtained for linkages with atoms of the third series of the periodic table, that is, atoms consisting of a nucleus and two shells of electrons. The values approximate to 50 kcal. except in the case of silicon.

The value is 110 kcal. for the linkage with hydrogen, the sole member of the first series of the periodic table.

From these facts, it may be deduced that:

(1) The energy of formation of the linkage of an element with oxygen is proportional to the covalency of the atom of that element, depends on the number of electron shells in that atom, and is not affected directly by the nature of the nucleus; (2) the 'energy of transfer' of an electron on oxidation is approximately the same for all atoms with the same number of electron shells, and is smaller the greater the number of shells.

More data are needed before other linkages can be tested on these lines. T. C. SUTTON.

Observations on Filmed and Filtered Vowels

PROF. E. W. SCRIPTURE [1] has put forward a theory of the construction of vowel sounds, from which he concludes that " a vowel profile is a course of air vibration, muscular movement, nerve currents, and inner (psychic) activity ". In support of this he says: " [the vocal cavity] does not consist of a set of cavities connected by orifices but of one cavity of complicated form that cannot be analysed into separate cavities. . . . The shape of the vocal cavity is never constant for even the briefest instant; it is constantly and continuously changing according to the muscular movements that regulate it." These suppositions require some amendment.

Until Sir Richard Paget made the first artificial vowel models in plasticine,[2] there was admittedly some doubt as to the action of the vocal cavity, but the experimental fact that a true vowel sound may be excited in a rigid cavity disposes of the view that the muscular flexibility of the mouth has any serious influence on the form of the complex sound produced. Nor is it true that the vocal cavity is a single one of complicated form. In all vowels two dominant inharmonic resonances can be detected,[3] arising from the division of the mouth by the tongue into two distinct cavities. In the 'front' vowels (as in 'eat, it, hay, men, hat') it would appear that 'resonant' vibration takes place in the larger rear cavity, and stationary vibration in the smaller front passage,[4] an arrangement similar to the modes of vibration of air in a flask with a long neck of narrow oval section. (This result was actually foreseen by Helmholtz.) The modes of vibration are then determined by the equation

$$\tan mh \,.\, \tan mk = \frac{a}{A},$$

when the 'neck' is of length h and area a, and the rear cavity of length k and area A. In this instance, experiment has shown good agreement with this modification of the general theory of the double resonator.[5] The nature of the 'middle' and 'back' vowels is clear by experiment, but cannot at present be verified by theory owing to the great difficulty of bridging the gap between 'resonant' and 'stationary' vibration. The gap, of course, only exists in our range of mathematical tools.

The subject of compound resonance has been much confused in recent years by the use of mechanical and electrical analogies, many of which are misleading and some definitely at fault.[6] Branches of acoustics to which the electrical analogy has been successfully applied, such for example as the 'fingering' of the flute, can usually be treated quite as easily, and always with more understanding, by the application of classical theory, and particularly by the use of those methods, now neglected, so beautifully presented by Lord Rayleigh.

Sir Richard Paget's work leads to the conclusion [7] that " the ear judges a vowel by the form of the compound wave. The ratio of the amplitudes is possibly quite as important as the ratio of frequencies, and a resonator is only successful in imitating a vowel when both ratios can be reproduced." This is in agreement with Prof. Scripture's hypothesis that " the vowel character depends on the general shape of the vibration profile ". W. E. BENTON.

Isotopes of Uranium

WE have succeeded in finding evidence of several isotopes of uranium which emit alpha-rays. In the expectation that the proportion of actino-uranium would be larger the younger the mineral, uranium from Colorado carnotite was used, the age of which has been variously estimated at from 170,000 to 7,000,000 years. The half-periods estimated by Wilkins [1] and by Rutherford [2] for actino-uranium, from quite different methods of reasoning, were 2·5 and $4 \cdot 2 \times 10^8$ years respectively. The corresponding alpha-ray range would be about 3·2 cm.

In the present work, the alpha-rays from a very thin sputtered film of uranium fell at various angles on a special, fine-grained photographic emulsion 30μ thick, the grain distribution of which was shown to be independent of depth. The number of grains in the track of an alpha-ray in the emulsion was counted. A typical frequency curve for polonium is shown in Fig. 1, *A*, and for uranium in Fig. 1, *B*. The peak for the polonium rays is at 13 grains. The peaks in the uranium curve at 9 and 11 grains are taken as due to U I and U II. These three ranges agree with Laurence's values of the relative ranges of U I, U II, and Po. The analysis of the curve has not been completed but other alpha-rays of a subsidiary series with distribution peaks at 11, 13, and 16 grains seem indicated.

A peak at 11 grains might very well be due to actino-uranium. Those at 13 and 16 grains would indicate isotopes the ranges of which are remarkably close to proto- and radio-actinium.

The analysis of the curve is complicated not only by the fact that the relative abundance of the alpha-rays of the two series is unknown, but also that the shape of the frequency curve of a given member changes with the range. Data have, however, been secured on this latter point. A study of the former using uranium from various geological horizons is expected to give an attractive method for determining the ages of rocks which appears to be free from errors inherent in the method based on U/Pb ratios. For the very recent uranium used in this work, the uranium and actinium isotopes seem to be about equally active.

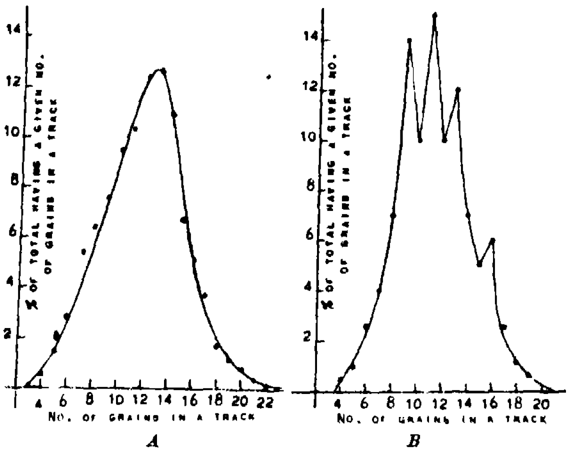

FIG. 1.—Typical alpha-ray frequency curves. *A*—Polonium. Polonium source above special laboratory lantern, emulsion 30μ thick. Data on 1038 tracks. *B*—Uranium. Sputtered uranium source above a special laboratory lantern, emulsion 30μ thick. Data on 2367 tracks. I—436, II—441, III—454, IV—544, V—492.

The Influence of Asia

JUST recently there has loomed in the mist of the past some wider conception of historical beginnings. By stating these we may awake attention to any further detail that may clear the view; the ideas may be modified when we come to close quarters.

A wide movement seems to take place periodically from the Caspian region to Syria and Egypt. Saladin the Kurd with his Turkoman troops conquered Syria and Egypt by A.D. 1170. About 950 B.C., models of box wagons and wheels, like those of Anau and Assyria, are found in Palestine, brought by Eastern migrants, who were probably the followers of Sheshenq (named from the Persian deity "He of Susa"), who conquered Egypt 940 B.C. By 2370 B.C. the Hyksos swept into Egypt, using the horse, and the toggle pin for dress fastening, usual in the Caspian region. At 3100 B.C. a skilful race of builders, using the toggle pin, and daggers with raised ribbing, both belonging to the Caspian basin, conquered Palestine and Egypt, as the Seventh Dynasty. An Asiatic movement about 5500 B.C. brought lazuli and the use of the face-veil into Egypt. Long before that, the names of the principal sites of the Caucasus were embedded in the Osiris mythology of the Egyptians, brought with emmer wheat from that region by the Badarians, who were certainly Asiatic. Each of these invasions helps our understanding of the others.

Another serial connexion begins with the celebrated ivory carving of Gebel el Araq (4800 B.C.?), bearing figures of animals that are unsurpassed for truth and grace; it belongs certainly to Elamite art, and exhibits the conquest of Egypt by the dynastic race coming from the Persian Gulf. Three or four centuries later there was a school of fine ivory carving—as the old king from Abydos—and after a similar interval the finest minute portrait carving of Khufu in ivory. It seems impossible to suppose a race re-inventing such skill disconnectedly; it is an obvious series. That compels us to assign the highest Egyptian sculpture of the pyramid age to a Persian origin.

The group of a deity restraining lions, on the same ivory of Gebel el Araq, is the first known example of a long train of such emblematic groups, where a god or goddess subdues horses, bulls, swans, wolves, or snakes, as a symbol of power over Nature, a symbol which pervaded Persia, Mesopotamia, early Greece, and Italy. Again western Persia has been the starting point. All of this indicates the link of civilisation between the Indus and Tigris which has been demanded by recent discoveries. The dates stated above are those given by the Egyptians.

Selection and Growth in Shore-Crabs

PROF. J. B. S. HALDANE in his new book entitled "The Causes of Evolution", p. 89, quotes the late Prof. Weldon as his authority for the statement that when the breakwater was built across the mouth of Plymouth Harbour, "the water inside became muddier, and the shore-crabs developed roomier gill-chambers". This is a complete mistake—in fact, a double mistake. Prof. Weldon did not assert that the branchial cavities of the shore-crabs had become larger, and what he did assert was shown by myself at the time to be incorrect. The subject is discussed in detail in my "Modern Biology" (1928), pp. 189-199.

The conclusion actually drawn by Prof. Weldon was that the increase of sediment in the water had, by selection, caused a decrease in the relative frontal breadth, which involved a better filtration of the water entering the branchial chambers. One point of my criticism was that efficiency of filtration could not be dependent upon a *relative* size of aperture, but must be proportional to the absolute size of aperture. The efficiency of a sieve is proportional to the size of the meshes, not to the total diameter of the sieve. Prof. Weldon's figures show that while the relative frontal breadth in thousandths of the carapace length was decreasing with increase in that length (that is, with the growth of the crab), and also in 1895 and 1898 as compared with 1893, the absolute frontal breadth increased in each year from 8 mm. to 11 mm. as the carapace length increased from 10 to 15 mm., and showed no decrease at all in one year as compared with another.

What Prof. Weldon actually investigated, therefore, was not a case of selection but a case of differential growth. The change of shape in the growing crab was known vaguely before; Prof. Weldon investigated it quantitatively in minute detail. But he did not show that the filtration of the water entering the branchial chambers depended on the relative frontal breadth, and he did not state that there was any relation between increased sediment and enlarged branchial chambers.

Research Items

Indians of Matto Grosso, Brazil.—Ethnographical and archæological results of an expedition through Matto Grosso, Brazil, to the head waters of the Xingu River in 1931 are described by Mr. V. Petrullo in the *Museum Journal* (Philadelphia), vol. 23, pt. 2. A number of tribes were visited, of which one, the Tsuva, had not previously been recorded, while three, the Kalapalu, the Kuikutl, and the Naravute, had not been described. At the head waters of the Xingu, although three widely distributed linguistic stocks are represented and they are surrounded by a fourth, no appreciable difference of material culture is to be observed. The villages are composed of a few houses around a clearing. The men's house is of inferior construction, and although it is the men's meeting place, it is not used for sleeping. It serves for ceremonial uses and for the entertainment of guests only, while the men of the village sleep in their own family dwellings. Usually several families live in one dwelling; and a young man on marriage lives in the house of the bride's father until he is in a position to build a house for himself. Women are the authoritative persons of the village. Inheritance and descent proceed through them; and although the men deal with strangers, the women must be consulted and their concurrence obtained before any arrangement may be concluded. Marriage is monogamous, but only as a matter of practical and economic convenience. Headmen sometimes have two wives. Most of the groups cultivate nothing but manioc, though some have maize. The Yawalapiti keep maize effigies suspended from the rafters of their huts. These are made of an ear of maize embellished with legs, arms, a skirt, and a painted visage. Some images are in the form of birds. In one village a harpy eagle was kept in a conical structure, and every man had to share with it the proceeds of his hunting or fishing, receiving in return a feather when its plumage was ceremonially plucked.

Inherited Differences in Taste Reactions.—It has recently been shown that individuals differ in their capacity for tasting certain substances, and that these differences are inherited. The results of an experiment with phenyl-thio-carbamide, made at the New Orleans meeting of the American Association for Advancement of Science last December, are recently published by Dr. A. F. Blakeslee and Dr. A. L. Fox (*J. Heredity*, vol. 23, No. 3). Of 2550 persons tested, 65·5 per cent tasted the substance as bitter, 28 per cent found it tasteless, while 2·3 per cent found it sour, and 4·2 per cent reported another taste. Earlier tests of families had shown that the failure to taste it is inherited as a simple Mendelian recessive. When both parents are non-tasters, all the children are the same. This is found to be the case in 39 children from such parents. Individuals also differ in the threshold of stimulation, some being able to detect the taste in a few drops of a 1/500,000 solution, while some non-tasters require a hot saturated solution to perceive any taste at all. This substance, which is bitter to most people, differs from dalcin, which is three hundred times sweeter than sugar, in that an atom of oxygen is replaced by sulphur. The related *p*-ethoxy-phenyl-thio-carbamide is identical in taste, but apparently gives a slightly weaker reaction. Similarly fumar-proto-cetraric acid, a bitter constituent of certain lichens, distinguishing them from closely related species, is tasteless to some, while others find it bitter in varying degrees. The odours of certain verbenas and freesias are also found to produce various sense reactions in different individuals, some finding particular varieties odourless. By tests of this kind, inherited differences in our sense organs are coming to light (see also NATURE, **129**, 735, May 14, 1932).

Pig-feeding Experiments.—The first Pig-feeding Report of the Harper Adams Agricultural College summarises the experiments in pig-feeding carried out between 1926 and 1931. Briefly, these showed that a ration of cereal meals was deficient in proteins and certain minerals for the needs of a rapidly growing pig, but that extracted soya meal, supplemented by lime and salt, gave as good results as fish meal when added to a cereal ration. An average proportion of about eight per cent of soya meal was found to be adequate, this being best secured by using about twelve per cent in the ration for a newly weaned pig, and gradually reducing this to a minimum of 5 per cent at bacon weights. A mineral allowance of $1\frac{1}{2}$ lb. limestone and $\frac{1}{2}$ lb. salt per 100 lb. mixed meals was sufficient, and this seemed to be as effective as the more complex and expensive mixtures containing a great variety of minerals. For sty-fed pigs under normal conditions, about 3 lb. of water per 0·1 lb. meal were needed for young pigs, but this amount could be reduced to $1\frac{3}{4}$ lb. at bacon weights—a little more being allowed in hot weather. Many factors affect the economic value of milk in pig-feeding, and although whole milk gave a higher rate of gain than separated milk, yet the financial returns were lower than those obtainable by feeding separated milk, in conjunction with butter-making or cream-selling.

A Fresh-water Medusa from China.—T. Fujiwara (*J. Science*, Hiroshima Univ., Ser. B, Div. 1, vol. 1, 1932) collected, in August 1930, specimens of a fresh-water medusa from a pool about fifty miles south-south-west of Shanghai. They were all males and were present in large numbers, but the hydroid stage was not found. The author considers that the sex of the medusæ is not dependent, as has been suggested, on the temperature of the water but on that of the hydroid stocks. He reviews the records of fresh-water medusæ in eastern Asia and gives an account of the principal characters of his specimens, dealing in some detail with the statocyst, and he states that the ring-nerve is single. He does not actually state the species of his medusa, but remarks that it agrees in a good many points with *Craspedacusta sowerbyi*, var. *kawaii* (Oka, 1907), which he considers should be separated as a species *C. kawaii* from *C. sowerbyi*.

Chromosome Cycles and Sexuality in Sporozoa.—In a memoir (*Mém. Soc. de Phys. et d' Hist. Nat., Genève*, vol. 41, fasc. I. 1-223, 150 text-figures, 1931) on the Sporozoa with special reference to their chromosome cycles and their sexuality, André Naville gives an account of the present knowledge on the life-cycles and cytology of the Neosporidia and the Telosporidia. In a discussion on the fundamental distinctions between the Protista and the Metazoa, he expresses the view that this appears to consist in the absence in the Protista of autonomous somatic elements, but he points out that in the Myxosporidia and the Actinomyxidia there are non-generative cells which may be regarded as somatic. There are no corresponding cells in the Telosporidia, a difference which confirms the prevalent view that these two groups are distinct. In the last part of the work the author states his views, rather as a working hypothesis than as a real theory, on sexual polarity, not only in the Sporozoa but also in other animals and in plants. As an example of this polarity in the Sporozoa may be

cited the Adeleida, in which the polarised gametoblast produces a number of gametocytes at each of its two extremities—one group male and the other female. In the Metazoa, among the examples considered are *Hydra*, *Ctenophora*, and *Sagitta*. The author adds a glossary of special terms and three synoptic tables in which the life-cycles and the conditions as to haploidy and diploidy, so far as they are known, are summarised for the Neosporidia, the Gregarinida, and the Coccidiomorpha respectively.

Tetraploid Tomato Plants.—Tetraploid plants of the common tomato, *Lycopersicum esculentum*, have been produced by several workers by decapitating the stem of a diploid. Some of the shoots which grow out from the callus are found to be tetraploid. Such plants show a variable amount of association of their chromosomes in fours and a certain amount of sterility. This was greatest in a tetraploid produced from a doubled haploid, and its fruits were smaller than in the diploid. Prof. E. W. Lindstrom, continuing this method (*J. Heredity*, vol. 23, No. 3), has recently produced a tetraploid from the currant type tomato, *L. pimpinellifolium*. This species and *L. esculentum* have the same chromosome number ($n=12$) and cross readily, although the hybrids show gametic sterility in F_1 and F_2. The tetraploid from *L. pimpinellifolium* is not only larger than the diploid in all parts, such as seeds, cotyledons, leaves, and fruits, but also it is highly self-fertile, although completely sterile in crosses with the diploid of either species. From it have been derived 248 mature plants in four generations. These segregated for red *v.* yellow fruits in the ratio 20 : 1, which suggests that random assortment of the eight chromotids may be taking place in meiosis. The origin of the yellow factor is uncertain, but may possibly have been from *esculentum*, as three later tetraploids of *L. pimpinellifolium* had somewhat smaller fruits than the first.

Oscillation of the Earth's Atmosphere.—In a recent memoir of the Royal Meteorological Society (No. 35, vol. 4), G. I. Taylor examines a suggestion that has been made to explain a discrepancy observed between the velocity of a free gravity wave in the earth's atmosphere given by tidal theory, namely 910 feet per second, and the values found by direct calculation and by observations of the air wave caused by the Krakatoa volcanic eruption or explosion of 1883, which come to about 1050 feet per second. The suggestion is that the discrepancy might be explained by supposing that rapid pressure changes take place adiabatically while those like the semi-diurnal pressure wave of the atmosphere are more nearly isothermal; it has been put forward by Prof. Taylor and by three other writers—Chapman, Pramanik, and Topping—who have discussed the theory of the oscillations of the earth's atmosphere in relation to observational evidence. Taylor shows that the above mentioned supposition is untenable because the transference of heat by radiation and conduction required to introduce an important difference in the speed of the wave from that consistent with adiabatic pressure changes must lead to so much damping that the amplification by resonance, required to give the observed semi-diurnal variation, even if the free period of oscillation were taken to be 12 hours instead of the customary period of 11 hours 56 minutes, becomes impossible. He finds, further, that the required resonance can only be arrived at if the time taken for an inequality of temperature to be reduced in the ratio e to 1 is greater than 76 hours. The upshot of this investigation is that the cause of the discrepancy between the theoretical value of the free period and the value 12 hours remains at the moment unidentified.

Composite Dyke of Breven, Sweden.—A detailed and stimulating investigation of the great Breven dyke has been published by T. Krokström (*Bull. Geol. Inst., Upsala*, 1932, pp. 243-330). The dyke has a length of 30 km., and ranges in width from 0·3 km. to 1·2 km. It is concluded from the results of geological, petrological, and chemical work that the exposures of the Breven dyke now visible represent a section of intermediate depth through a fissure that originally served as a channel for a series of extrusions all belonging to the same volcanic cycle. The material brought up by the successive eruptions probably emanated from a common magma reservoir, the different types of magma being along the normal line of differentiation within the reservoir (possibly accompanied by assimilation of the granite roof or walls). In chronological order the magmas corresponded to (*a*) olivine-dolerite; (*b*) olivine-free dolerite; (*c*) granophyre; (*d*) olivine-dolerite. During its ascent the granophyre altered the dolerite (*b*) by pneumatolytic action into an amphibole-rich, biotite-bearing intermediate type for which the name epidolerite is suggested. The latest olivine-dolerite is a restricted extrusion which took place after an epoch of denudation that uncovered the more deep-seated types of the dyke.

Intensities of Nebular Lines.—Bowen's conclusion that the characteristic spectra of nebulæ and certain novæ arise from improbable, but not completely forbidden, transitions in some light atoms and ions receives additional confirmation and some amplification from a theoretical investigation of the transitions by A. F. Stevenson (*Proc. Roy. Soc.*, August), in which their probability is calculated by approximate quantum mechanical methods. This is of particular interest as leading to an estimate of the density of the gas in the nebulæ, on the assumption that it must be sufficiently small to make the time between the collisions of atoms or ions at least the mean theoretical time for the lives of the initial atomic states involved in the radiation. The numbers so obtained seem reasonable, the required time being at least about twenty-six seconds in regions where the so-called nebulium lines are emitted, and at least about three minutes where the red lines $\lambda 6583 \cdot 6$ and $\lambda 6548 \cdot 1$ originate, but it has to be remembered that one important 'forbidden' line, the celebrated $\lambda 5577$ of the aurora, can be readily produced in the laboratory at pressures of the comparatively high order of a thousandth of an atmosphere.

Diurnal Variations in Cosmic Radiation.—Prof. A. H. Compton and a number of collaborators have given an account in the second July number of the *Physical Review* of the results obtained in measurements made on cosmic rays hourly for ten consecutive days, at an altitude of 3900 metres. The rays were recorded by the ionisation produced in a steel sphere of 10 cm. internal diameter, filled with air at 30 atmospheres pressure. The measurements were made relative to the effect of a radium source, a procedure which automatically eliminated a number of errors, and were finally averaged over the ten days and corrected for some pressure and temperature effects. It then appeared that the ionisation was $1 \cdot 5 \pm 0 \cdot 25$ per cent more between 8 A.M. and 4 P.M. than between 8 P.M. and 4 A.M., a result considered in satisfactory agreement with the results of other observers, if the variation is due to a soft component of the rays. It is suggested as a consequence that the inference previously made by Millikan and Cameron that the energy in the universe in the form of cosmic rays is comparable with that in the form of light is of doubtful validity.

Velocity of Light in a Magnetic Field.—It has been established with considerable accuracy by C. C. Farr and C. J. Banwell (*Proc. Roy. Soc.*, August) that the velocity of light in a vacuum of approximately one hundredth of a millimetre of mercury is unaffected by a transverse magnetic field. The optical system employed was a Jamin interferometer, in which the light paths were in fields of different strengths, one very small and the other of the order of 20,000 gauss. The whole apparatus was set up so as to minimise spurious shifts of the fringes, the position of which was watched by a number of observers as the field was established and switched off. The sensitivity of the apparatus was such that a relative change in speed of 1 part in 2×10^7 could have been apparent. By working with polarised light it was further shown that it was immaterial whether the direction of vibration lay in or at right angles to the applied magnetic field.

Diamagnetism of Bismuth.—Bismuth, which has always been of interest from its generally anomalous physical properties, has been the subject of much study recently in the form of single crystals. Goetz has confirmed in this way very strikingly the presence of an intermediate structure between the atomic lattice and the macroscopic crystals, giving for the average size of the discontinuities with which it is associated a few thousandths of a millimetre. In the April number of the *Indian Journal of Physics* it is pointed out by S. M. Rao that the existence of these sub-units of structure is in accord with the magnetic properties of the substance. Bismuth is diamagnetic, but the susceptibility depends upon the size of the particles used. Colloidal bismuth, when melted and recrystallised, shows an increase of up to thirty per cent in susceptibility, the change persisting even when allowance is made for contamination with oxide. The change of susceptibility with particle diameter is small for particles greater than about 1μ in diameter, but below this size falls off rapidly to the lower values, and for the smallest particles considered is still decreasing. The change in susceptibility thus occurs from about the particle size associated from other experiments with the mosaic structure, and affords confirmatory evidence for the reality of this.

Astronomical Topics

The Lunar Eclipse of Sept. 14.—This was the first lunar eclipse of considerable size that was observable in London under clear skies for a good many years. Lunar eclipses are of interest from the fact that they give a good idea of the general state of the earth's atmosphere, or at least of the portions of it over the regions where the moon is on the horizon. The amount of illumination within the shadow varies to a notable extent. In 1884 the moon could be seen only with great difficulty, while in 1895 the maria and other surface markings could be observed with ease. The late eclipse did not attain either of these extremes, but was perhaps somewhat darker than the average eclipse. The limb was discernible in the telescope without difficulty at all the stages of the eclipse, also the crater Aristarchus, which is the brightest point of the disc. The outlines of the maria, however, were not easily seen until the maximum phase was nearly reached; this is an effect of the darkening sky; when there is bright sky light over the eclipsed region, contrasts are more difficult to detect.

The part of the disc that was nearest the centre of the shadow was coppery in tint, but the parts nearer the edge of the shadow tended rather to bluish grey. There was a specially bright region at the north-east limb of the moon. As the moon traversed the northern portion of the earth's shadow, there was not much opportunity to test whether the air in the southern hemisphere was rendered opaque by dust from the recent eruptions in the Andes. The southern region of the moon was carefully watched; it did not appear that there was any greater darkening there than that to be expected from deeper immersion in the shadow. The next total eclipse at which the moon will be high, in Great Britain, is on Nov. 7, 1938.

Capture of Comets by Planets.—The theory that all the comets of short period have had their orbits changed from parabolas to ellipses by near approaches to the great planets has been subjected to adverse criticism lately; in particular, Mr. S. Vsessviatsky, in the *Observatory* for May last, indicated many points in which the theory gave results that did not accord with observed facts. M. Jean Bosler contributed another paper on the subject to the *Journal des Observateurs* for January last. It examines what proportion of the comets that make close approaches to Jupiter would have their orbits transformed into ellipses and hyperbolas respectively. He finds that the ratio between the two is nearly one of equality, but with a slight preponderance for hyperbolas. This is clearly a further argument, though not a very strong one, against the theory; for it had already been shown that even if all the close approaches had led to elliptical orbits, there would not be enough to maintain the supply of short-period comets; reduction of the number of ellipses by more than half would render the insufficiency still more marked.

It is not, of course, denied that such approaches may at times take place; but merely that they are insufficient to explain the large family of short-period comets. In fact, a case seems to have taken place recently; Ryves's comet, that was under observation a year ago, was shown to have approached Jupiter within a few million miles about a year earlier. A definitive orbit of Ryves's comet has not yet been computed; but those that are to hand make it somewhat probable that the orbit, after passing Jupiter, was hyperbolic.

A New Stellar Photometer.—Dr. W. H. Steavenson describes, in *Monthly Notices, R.A.S.*, for June, a simple form of photometer which has lately been inserted in his reflector. A plate of glass about a tenth of an inch thick is placed in the focal plane. Some small dents in its surface were made with a diamond, and illuminated by an electric bulb placed at the side of the tube, in the plane of the glass. The remaining light of the bulb is totally reflected in the plate, and does not reach the eye. The illuminated dents have a stellar appearance; their brightness can be adjusted by a rheostat to approximate equality with the star to be measured; the remaining difference is measured by a sliding wedge. The wedge projects beyond the eyepiece; its position for equality of light is recorded by marking on a card the distance of the end of the wedge from the tube, so that no artificial light is needed during the comparison. Ultimately the artificial star is compared with a known star in the north polar sequence. The different dents in the glass plate appear of different brightness, so that one can be selected near the magnitude of the object to be measured. Dr. Steavenson's extensive work on old novæ, etc., is well known. The new photometer should render the comparisons still more accurate.

The Value of Tuberculin Tests*

THE name 'tuberculin' has been applied to any extract, suspension, or other preparation of *B. tuberculosis* or of media on which it has grown. The Therapeutic Substances Regulations 1931 (Statutory Rules and Orders, No. 633) define the term in a more limited sense as preparations of fluid media on which the organism has been grown in artificial culture, which have been freed by filtration from the bacilli. When the filtrate has been concentrated it is known as 'old tuberculin'; its potency is measured by comparison with that of the standard preparation.

Although tuberculin is now scheduled under the Therapeutic Substances Regulations, the hopes originally raised that it would prove of value as a curative and diagnostic agent in tuberculous disease in man have not been completely satisfied. The diagnostic aspect of the problem has recently been investigated by P. D'Arcy Hart, who concludes that tuberculin tests are of definite value in certain circumstances, provided that the correct technique is observed. The Report is based on the examination of 1030 clinically tuberculous patients of all ages and types of infection, and 751 clinically non-tuberculous patients of all ages.

The intracutaneous or Mantoux test is recommended, since it is more sensitive than the cutaneous or von Pirquet test. The initial dose is 0·1 c.c. of a 1 in 10,000 dilution (in 0·5 per cent phenol-saline) injected into the skin of the forearm or upper arm. The result should be read at 48 hr. and 96 hr. A positive reaction consists of an area of erythema or erythematous infiltration the greatest diameter of which equals or exceeds 5 mm., or which is definitely greater than the reaction given by a control injection of the medium from which the tuberculin was prepared. If the test is negative, a retest should be carried out with a 1 in 1000 dilution; if this gives a negative response, a 1 in 100 dilution should be tried. A 1 in 10 dilution may be finally employed in confirmation. A positive reaction indicates hypersensitiveness of the tissues to a product, probably protein in nature, of the tubercle bacillus, and is probably only seen after tuberculous infection accompanied by the formation of histological tubercles has taken place. There is a significant interval between primary infection and the appearance of tuberculin skin reactivity. A positive response indicates merely that infection has occurred at some time in the individual's life, and not, on present evidence, that it is still active.

The positive reaction has its chief clinical value in infancy, when tuberculous infection is more likely than at other ages to be associated with, or to progress into, active tuberculous disease. The prognosis is worse the younger the patient and the more unfavourable the home conditions. An infant of less than two years, but without symptoms, should be kept under observation for several years. If obscure and persistent symptoms are present, the possibility of tuberculous infection as cause should be seriously considered. Between two and five years a positive reaction with persistent symptoms should suggest that the latter are tuberculous in origin: at more than five years of age this is much less likely to be the case. Quantitative tests, however, are of very doubtful value for estimating the prognosis in clinical tuberculosis.

A negative tuberculin reaction almost excludes the presence of tuberculous infection: with the 1 in 1000 dilution the average error in the author's series of cases was less than four per cent. With the 1 in 10 dilution, a negative reaction excludes clinical tuberculosis with an average error of a little more than two per cent (4 per cent in children up to five years of age, and 3·5 per cent in advanced cases of tuberculosis with marked toxæmia). The error is considerably greater with the 1 in 10,000 dilution, being 12 per cent. The usefulness of the test for the negative diagnosis of clinical tuberculosis depends also upon the chance of the patient giving a negative reaction should his condition, suspected of being tuberculous, be in reality due to some other cause. This chance is determined by the percentage of negative reactors among clinically non-tuberculous individuals of the same age and social status, and living in a similar environment. In Great Britain, the test can only be profitably applied for negative diagnosis, in patients of the hospital class in large cities, in childhood: in country and private practice it may also be of value in adults. The incidence of positive reactions in adults of the poorer classes in towns is too high to make a negative response of value.

Children from tuberculous households give a much larger percentage of positive reactions than those whose homes are free from this disease, and the percentage is greater when the tuberculosis is active or open than when it is closed or healed. Again, the incidence of positive reactions among children is greater when they live in contact with a tuberculous relative than when a tuberculous relative visits them only occasionally. The presence in the household of a sufferer from non-pulmonary tuberculosis does not increase the incidence of positive tuberculin reactions among the children. Infants separated from their tuberculous parents before infection has occurred and placed in healthy families appear to be no more liable to acquire infection in early life than the infants of non-tuberculous parents. All these facts suggest that the children of tuberculous families are more likely to acquire the disease than those from the non-tuberculous simply because they are more exposed to infection; in other words, no evidence of a hereditary predisposition to infection has been found by the author. Such a view is, however, not inconsistent with a conception of heredity as a determinant of the subsequent course of infection once this has taken place.

The practical conclusion from these results is that children should be kept out of contact with cases of pulmonary tuberculosis during the early years of their life, or that the chances of infection should be minimised by the careful hygienic control of the patient, such as that developed at the Papworth Settlement by Varrier-Jones. When it is considered advisable to separate the children, tuberculin tests will have an important rôle in determining which are the most suitable for this procedure.

The incidence of positive tuberculin reactions in a healthy community is an index of the risk of exposure which is determined by the frequency of open tuberculosis, the measures taken to combat it, the general hygienic standard of the population, and the infectivity of the milk supply. Unless tuberculosis can be stamped out and the population kept free from it, the development of a positive reaction in an otherwise healthy person is a favourable sign, since it indicates a degree of protection against the development of clinical tuberculosis. Natural tuberculous infection has a greater fatality in infancy than at other ages, so that it is advisable to postpone the first infection, if possible, to middle or later childhood, for example, by removal from contagion at home and by pasteurisation

* Medical Research Council. Special Report Series, No. 164: The Value of Tuberculin Tests in Man; with Special Reference to the Intracutaneous Test. By P. D'Arcy Hart. (London: H.M. Stationery Office, 1932.) 2s. net.

of the milk supply. It is, however, advantageous for the first infection to take place before adult life is reached, because of the partial immunity which may result. The evidence obtained from tuberculin tests in London school children suggests in fact that tuberculisation occurs chiefly in later childhood and adolescence, that is, when the principal activities of the individual are away from home.

It is hoped that further work will result in an answer to the question as to whether tuberculin sensitisation is decreasing in the population, following the improvement in general hygiene and control of tuberculosis. It is also to be hoped that an altogether satisfactory method of prophylactic immunisation will have been developed before the incidence of infection has fallen so much that the general population finds itself in the precarious unprotected state of a non-tuberculised race.

Winds and Weather on the Coasts of India

MR. S. BASU, of the Marine Section of the India Meteorological Department, Poona, has prepared a useful handbook on the winds and weather off the Indian coasts.* It is based, presumably, largely upon the logs of steamers of the merchant service voyaging in Indian waters, as well as on the work of meteorologists—notably Sir John Eliot—who have made a special study of the cyclones of this region, and is intended to be of service to Indian seamen. Assuming that the standard of accuracy to be expected of a professional meteorologist with extensive sources of trustworthy information has been maintained, this book should fulfil admirably the purpose for which it was written.

The most dangerous weather phenomenon with which the Indian seaman has to concern himself is of course the tropical cyclone. Tropical cyclones do not exhibit quite the infinite diversity of character shown by the cyclonic depressions of the North Atlantic, for they are definite vortices conforming to a fairly definite type. It is possible, therefore, to frame certain general principles that should be followed by a seaman who wishes to avoid exposing the vessel in his charge to the full fury of the inner circle of winds that so often attain to the full force of a hurricane. A special chapter is devoted to this problem, and contains hints as to how the exchange of weather information by radio between ships, together with the utilisation of the official weather reports issued by radio, can help in the navigational problem that arises when a ship approaches sufficiently near to a cyclone.

Another source of danger is the 'Nor'wester', a thunder-squall of early summer that is believed to have given rise to winds of more than a hundred miles an hour. It is primarily a land phenomenon, but is felt sufficiently far out to sea—70-80 miles out, according to the account of it given in the second chapter of the work—to be a menace in the Bay of Bengal.

In addition to information about the more violent weather phenomena, there is much useful matter relating to ordinary local winds and currents and their seasonal variations, and to tides. The last chapter describes the system of visual storm warnings in force throughout Indian waters.

The handbook is well arranged; the standard of printing is adequate, while the maps are clear in spite of their small size. It is not easy for a reviewer in Great Britain to accept the Director-General of Observatories' request for practical suggestions for increasing the usefulness of future editions—unless of course it is proposed to increase its length, in which case much additional information about local peculiarities in the weather could doubtless be included.

Electric Discharge in Gas at Low Pressure

DR. I. LANGMUIR presented an interesting review of the electrical properties of the discharge in gas at low pressure, at the recent International Electrical Congress held at Paris. The advances made in this field in the last nine years, which have completely revolutionised our outlook, have come largely from his laboratory and from that of Prof. K. T. Compton.

In his recent paper, Dr. Langmuir confined himself to a statement of the more important mathematical relations which have been developed to give a starting point, somewhat simplified still in comparison with reality, for the investigation of discharges. In these there are two fundamental conceptions, that of a 'sheath' and that of a 'plasma'. Sheaths are found in general on the surfaces of electrodes or on the walls of the tubes, and are essentially regions in which there is a strong separation of charges of one sign. In practice these are usually positive, but by control of the potential of the solid boundary, they may be made of the opposite sign. The potential within them is governed by the well-known Poisson equation for the divergence of the electric intensity, and the currents across them determined chiefly by the rate at which particles from the main discharge diffuse to their boundaries.

The plasma is, on the contrary, a region in which the concentrations of electrons and positive ions are almost equal and opposite, and usually both large, of the order of 10^{8} to 10^{13} per c.c. It has thus a high conductivity, in distinction to the sheaths, and almost invariably in the discharges studied by Dr. Langmuir, has exhibited the peculiarity that the distribution of velocities amongst the electrons in it has been Maxwellian, with a temperature between 5000° and 100,000°. The determination of these temperatures, and the simultaneous analysis of other features of the plasma, is perhaps the most valuable contribution to a more general theory of discharges from this work, and can be accomplished by taking the current-voltage characteristic curves for an exploring electrode. At the present time, the chief advances are being made as a result of the departures which have been observed from Dr. Langmuir's original theory of exploring electrodes, and it is clear that the conception of an electron temperature will have to be modified in certain cases.

It is interesting to notice that there are two distinct reasons why parts of a discharge tube may be non-luminous, or almost so. One is, that a sheath is present; and the other, that although in a plasma, which is usually brightly luminous, the discharge is being carried by diffusion, often in a reversed electric field, so that the electrons are not acquiring sufficient energy to excite or ionise the molecules of gas.

Calendar of Geographical Exploration

Sept. 27, 1874.—Crossing Western Australia

J. Forrest reached the overland telegraph line, which had been carried from Port Darwin to Adelaide in 1872, after a journey which began at Perth. He had followed the Murchison River and, after that, a line of springs. By August this source of water had given out, and it was with the utmost difficulty that he achieved his object and reached the line south of the Alberga River, thus completing the link between the coast lands of the west and the central regions. In 1869, Forrest had proceeded from Perth to the region west of Lake Barlee, and in 1870 had followed Eyre's route in the south, starting, however, from the west.

Sept. 28, 1791.—Coastal Surveys in Australasia

A French expedition under Bruni d'Entrecasteaux left Brest to search for La Pérouse. Surveys were carried out in Tasmania and New Caledonia, Bougainville Island was visited, and Amboina was reached through the strait between New Britain and New Ireland. The south coast of Australia was charted to 131° 30′ E., and the islands east of New Guinea, with the coast of New Guinea itself, were charted. Shortly after surveying New Britain, d'Entrecasteaux died. The explorer's careful work did much to fill in the details of this region of the Pacific. A competent scientific staff accompanied the expedition, the naturalist, Labillardière, afterwards publishing his records, while the hydrographers, Rossel and Beautemps-Beaupré, published the journal of d'Entrecasteaux and the charts of the coasts visited.

Sept. 30, 1500.—Brazil and the Mouth of the Amazon

Vicente Yanez Pinzon, who had formerly sailed with Columbus, reached Spain after a voyage which had been successful from the point of view of discovery, though two out of his four vessels were lost in a storm. He sailed in December 1499 from Palos, passed the Cape Verde Islands, and penetrated so far to the south-west that he lost sight of the pole star. On Jan. 20, 1500, he sighted the Brazilian Cape of San Agustin. Pinzon was the first to land on the American continent south of the equator, his farthest south being 8° 20′ S. In April of the same year the Portuguese, Cabral, also sighted the coasts of Brazil. Following the coast northward to the equator, he discovered the mouth of the Amazon, finding the water still fresh forty leagues out at sea.

Societies and Academies

London

Institute of Metals * (Annual Autumn Meeting), Sept. 14.—**C. E. Ransley** and **C. J. Smithells**: Mechanical properties of nickel wires. The materials used include commercial nickel, refined nickel prepared by melting in hydrogen, and the same material with small additions of the elements commonly present in commercial nickel.—**H. J. Gough** and **D. G. Sopwith**: Atmospheric action as a factor in fatigue of metals. A review of the literature of corrosion fatigue reveals many apparent inconsistencies, but a closer examination indicates that such is not the case. It is shown directly that atmospheric corrosion enters, to a varied extent, into the mechanism of fatigue as exhibited during the usual type of fatigue test in which the surface of the specimen is exposed freely to the atmosphere.—**G. I. Taylor** and **H. Quinney**: The distortion of wires on passing through a draw plate. Composite copper wires ½ in. in diameter, each consisting of two wires of semi-circular section, were pulled through various draw-plates. Photographs are reproduced showing the distortion of the cross-sections. These are treated in a quantitative manner, measurements of the ratio of distortion to increase in length being found for various reductions in area and angle of taper.—**H. W. Brownsdon** and **L. C. Bannister**: A modified impingement corrosion apparatus. Owing to difficulties experienced with apparatus hitherto used for carrying out impingement corrosion experiments, a modified apparatus has been devised which is simple in design and permits of the ready control of the many factors influencing this type of corrosion; details are given regarding its construction and use.—**W. H. J. Vernon**: The open-air corrosion of copper. (3) Artificial production of green patina. Treatment with ammonium sulphate solution followed by a solution in which basic copper sulphate is suspended gives a green patina, which, however, breaks down under severe weather conditions. A patina stable under the latter conditions is produced by anodic treatment for 15 minutes in a suitable electrolyte; it has a good green colour and is quite insoluble in water. Certain synthetic coatings other than basic copper sulphate, although initially green, readily blacken on free exposure to town air. The application of linseed oil, and more especially of lanoline, to the primary coating gives marked protection to the underlying metal, but does not prevent discoloration; water glass and silicon ester, on the other hand, appreciably increase the corrosion.—**K. L. Meissner**: Two years' corrosion tests with duralplat in the North Sea. The specimens consisted of strips of four different thicknesses, drawn profiles of two thicknesses, and riveted strips. With the exception of the last mentioned, all samples were exposed in two series, that is, at ebb and flow of the tide, and always under water. Samples were taken every three months.—**T. G. Bamford**: The properties of commercial varieties of copper at high temperatures. Five typical commercial coppers were examined. All these varieties were capable of resisting shock extremely well up to 400° C., and with one exception—that of tough-pitch arsenical copper—impact strength was well maintained up to 600° C. In general, nickel-copper has the greatest, and tough-pitch pure copper the least, capacity for withstanding alternating stresses at elevated temperatures, although the capacity varies considerably from one temperature to another. Nickel-copper has exceptionally high endurance at a temperature of 560° C.

* Continued from p. 446.

Paris

Academy of Sciences, Aug. 8 (vol. 195, pp. 405-428).—**Gabriel Bertrand** and **Georges Brooks**: The constitutional formula of laccol. The authors have obtained laccol in well-defined crystals, have prepared its tetrahydro-derivative, and have converted the latter into the diacetate. Laccol is a derivative of pyrocatechol, $C_6H_3(OH)_2C_{16}H_{29}$.—**J. Schokalsky**: The fluctuation of the arctic climate. Evidence that during the last thirty years the Atlantic current has carried an enormous mass of warm water into the polar basin. As a result, there is now a period of a milder polar climate.—**N. Cioranesco**: Some properties of polyharmonic functions in correlation with certain properties of polynomials.—**L. Tchakaloff**: A property of trigonometrical polynomials.—**F. Marty**: The group of automorphy of certain integral functions.—**A. Silveira** and **E. Bauer**: The Raman effect in saline solutions.—**Duffieux** and **Léon Grillet**: A sensitometric arrangement with cylindrical lens and dia-

phragm in profile.—**Léon Gion**: The photochemical oxidation of aqueous solutions of ammonia. Ammonium nitrite results from the oxidation, and this is decomposed photochemically.—**Astruc and Mousseron**: The double sulphate of aluminium and sodium. The existence of sodium alum is clearly proved, but it is only a true double salt between the temperatures 11° C. and 39° C.—**V. Frolow**: The condition of the dissolved salts in the waters of the rivers of the Damas region.

CRACOW

Polish Academy of Science and Letters, June 11.—**Georges Bouligand**: The essential isolated singularities of a harmonic function and various associated problems.—**S. Mazurkiewicz**: Ensembles of unicity.—**S. Szczeniowski**: The probability of the passage of an electron in a region of negative energy.—**Mlle. J. Goworecka** and **M. Hlasko**: The electrolytic conductivity of the alkali metal hydroxides in water and the mobility of the hydroxyl ion. The limiting conductivities of lithium, sodium, and potassium hydroxides have been determined, the values found being higher than those generally accepted.—**K. Dziewoński** and **Cz. Piasecki**: Syntheses of the monosulphonic derivatives of acenaphthenequinone.—**K. Dziewoński** and **Mlle. Z. Zalewska**: A new method for the synthesis of dinaphthopyrone.—**A. Swaryczewski**: The *d*-tartrate of guanidine: crystallographic study.—**J. Zerndt**: An attempt at the determination of the age of the blocks of coal from the Carpathian Flysch by means of the megaspores.—**W. Tad. Dominik**: The relation between the formation of crystals of calcium oxalate in certain Coniferæ and the fall of the leaves. —**Z. Kolodziejski**: Study on the regeneration of the pedal disc in *Actinia equina*.—**J. Zaćwilichowski**: The innervation and the sensitive organs of the oviscapt in *Allantus arcuatus* (Tenthredinoidea).

GENEVA

Society of Physics and Natural History, June 2.—**Ch. H. Wakker** and **E. Briner**: Researches on the chemical action of electric discharges: improvements in yields realised by using light metal alloys as electrodes. The presence of alkali or alkaline-earth metals in the electrodes of arc furnaces considerably increases the energy yields in the production of various substances, especially nitric oxide.—**Ch. H. Wakker, E. Briner**, and **H. Paillard**: Researches on the production of nitric oxide in an arc furnace working with electrodes of light metal alloys. The improvements in the energy yields in the production of nitric oxide by means of the arc realised by incorporating small proportions of the alkali or alkaline earth metals in the electrodes are reproduced in a furnace using 2-4 kilowatts and with arcs 40-60 cm. in length.—**A. Lombard** and **A. Coaz**: The limit between the Jurassic and the Cretaceous from the Col des Aravis to the Col du Sageroux, Haute Savoie. The authors have recognised the existence of a zone of passage in the fauna of which the true Jurassic forms progressively disappear. There is no clear-cut line between the two periods.—**D. Zimmet** and **Ch. Yung**: The difference between the nitroprusside reaction for glutathione and acetone: the effect of the hydrogen ion concentration. Sodium nitroprusside gives a rose-violet colour with glutathione and with acetone, but whilst the first reaction is produced immediately and reaches a maximum at pH9, the reaction with acetone is not produced with pH less than 9 and is slow between pH9 and pH10. Reagents are proposed for detecting glutathione even when acetone is present. —**D. Zimmet**: A new reaction of glutathione. Oxidised glutathione, like cystine, gives a persistent rose-violet coloration with silver nitrate and dimethyl-p-phenylenediamine. These two reagents alone give only a fugitive tint. Reduced glutathione prevents any coloration, unless it is first left in contact with silver nitrate.

ROME

Royal National Academy of the Lincei, April 3.—**F. Severi**: A fundamental property of the fields of holomorphism of an analytical function of one real variable and one complex variable.—**P. Burgatti**: A classification of the linear equations of the second order to the ordinary derivatives founded on recurrent relations.—**G. Fubini**: A theorem on the equations to the partial derivatives of elliptic type which generalises a theorem of Hartog and one of Severi.—**M. La Rosa**: The supposed reality of the Lorentz contraction and the determination of the absolute motion of the earth. —**A. Pochettino**: The Hallwachs effect of compounds of elements with two-fold valency. Whereas, in general, Mn^{III} and Mn^{VII} ions tend to undergo transformation in the light into Mn^{II} and Mn^{VI} ions respectively, manganous hydroxide becomes changed into manganic hydroxide. Whilst calomel shows a tendency to become converted in the light into corrosive sublimate, this undergoes the reverse change under similar conditions, so that an equilibrium is established between the two; the same thing happens with cuprous and cupric chlorides. In general, with various pairs of analogous compounds, the greater Hallwachs effect is always shown by that compound in which the element of variable valency has the lower valency, independently of the sign of the ion in which the element appears.—**M. Betti** and **P. Pratesi**: Chemical constitution and rotatory power: Derivatives of chloro- and bromo-benzaldehydes. The anomalies displayed in the values of the dissociation constants of chloro- and bromo-benzoic acids are reflected in the rotatory powers of corresponding aldehyde *o*-derivatives. Thus, the dissociation constants of benzoic, *o*-chloro-, and *o*-bromo-benzoic acids are 0·006, 0·132, and 0·145 respectively, and the molecular rotations of the compounds formed by benzaldehyde, *o*-chloro-, and *o*-bromo-benzaldehyde with *d*-β-naphtholphenylaminomethane are +373·1°, −128·4°, and −308·7° respectively. Similar results are furnished by the meta- and para-derivatives, all the data indicating that, in these compounds, bromine is distinctly more highly electro-negative than chlorine. —**U. Broggi**: Complete linear differential equations with constant coefficients.—**A. Masotti**: Relations between the curvatures of two corresponding lines in a conform representation.—**J. Rey Pastor**: Topology of the dominions of a space of n dimensions.—**P. Rocher**: Lines of greatest slope of Green's function. The fact that the arc of greatest slope of Green's function, passing from the pole A to any point B of the domain, does not depend symmetrically on A and B, is extended to Euclidean spaces of more than three dimensions.—**Ruy Luis Gomes**: The existence of the normal derivative of a simple layer potential.—**L. Campedelli**: Certain noteworthy double planes with curve of branching of the tenth order.—**G. Palozzi**: Some results of projective-differential geometry.—**G. Colonnetti**: Influence of the shearing force on the deflection of a beam. Mesnager's statement that the elastic deflection of an inflected beam does not depend on the shearing force, is shown to be erroneous.—**A. Rosenblatt**: Laminary movements of incompressible viscous liquids (4).—**A. Occhialini** and **L. Gallino**: A reproducible sphinterometer for quantitative spectroscopy. For quantitative spectroscopic purposes, use may be made of the fact that a radiation emitted, on the passage of a spark, from a metal contained in an electrode is derived from a region adjacent to the electrode and of length varying with the richness in

the electrode of the metal considered. The instrument described depends on this principle.—**P. Straneo**: Energetic tensors in the unitary theory of absolute geometrisation.—**G. B. Bonino and P. Cella**: Raman spectrum of certain derivatives of aniline. The presence of a C : N linkage in a molecule results in the appearance in the Raman spectrum of one or two lines between 1400 cm.$^{-1}$ and 1500 cm.$^{-1}$. These lines cannot be confused with the lines 1430 cm.$^{-1}$-1450 cm.$^{-1}$ of the CH_2 group, which does not occur in the compounds examined.—**G. B. Bonino and P. Cella**: Raman spectrum of Δ^2-dihydronaphthalene. This spectrum exhibits lines in complete accord with the structural formula, if the spectra of naphthalene, decaline, and tetraline are taken into account. The line 3041 cm^{-1} of the aromatic C-H group occurs also with tetraline and naphthalene, and the lines 2873 and 2825 observed are attributed to CH_2. The line 1663 is lacking with tetraline, decaline, and naphthalene and is characteristic of the double ethylene linkage; the line 1433 is the characteristic CH_2 line but is displaced by 20 units from the typical CH_2 line.—**G. Piccardi and A. Sberna**: Molecular spectra and spectroscopic analysis (4): scandium. The method previously described allows of the ready and certain detection of 5 parts of scandium per 100,000, its superiority over ordinary spectroscopic methods being confirmed.—**F. De Carli**: (1) Solubility of calcium gluconate in the presence of sodium phosphate and of arsenious acid. Sodium phosphate has a less effect than boric acid in increasing the solubility of calcium gluconate, the most concentrated solution obtainable containing 7·26 per cent of the gluconate and 41·62 per cent of the phosphate. A 5 per cent solution of arsenious anhydride dissolves 9·29 per cent of the gluconate.—(2) Properties of solutions of calcium chloride and urea. Mixed solutions of calcium chloride and urea contain no molecular associations detectable by the physical methods employed. The therapeutic behaviour of such solutions does not appear to be attributable to specific properties of the compound, $CaCl_2$, $4CO(NH_2)_2$, $2H_2O$, but is probably due to an influence of the urea on the inconveniences sometimes accompanying the hypodermic administration of calcium chloride.—**T. Carpanese**: Granite, vesuvian, ilmenite, and titanite from Monte Rosso di Verra (Monte Rosa group).

VIENNA

Academy of Sciences, June 30.—**Richard Weiss and A. Beller**: Condensation of αα′-diphenyl-ββ′-benzofuran with unsaturated compounds.—**Heinrich Graven**: A method for determining uranium and thorium in minerals (2).—**Heinrich Gräven and Gerhard Kirsch**: The radioactivity of early pre-Cambrian granites from southern Finland. Non-metamorphic intrusions appear to be moderately homogeneous as regards radioactivity, although specimens of outstanding activity occasionally occur. The results obtained with these granites are, in general, comparable with those found by Mache and Bamberger for the central gneiss of the Alps.—**Hans Pettersson and Josef Schintlmeister**: Atomic fragments of small range from rare gases.—**Georg Koller**: A synthesis of methyl diacetylevernate and of methyl tetra-acetylgyrophorate.—**F. Lauscher, F. Steinhauser, and M. Toperczer**: Profile of the intensity of the sun's radiation through the Styrian and Lower Austrian Alps. At the time the observations described were made (July 30-Aug. 2), the atmospheric dew of the E-N-E. air-movement led to the formation of a layer of vapour at the cumulus level over the whole pre-Alpine region. Hence the intensity of the solar radiation in the higher parts of the pre-Alpine district was somewhat below that of the inner Alpine valleys. At medium heights (about 1000 metres), the mountain air weakened the radiation about ten times as much as absolutely pure air, this observation agreeing with those made elsewhere. At about 700 metres the weakening was fifteen-fold and at 450 metres twenty-two-fold.—**H. Kun and H. Burchardt**: Non-specific actions of the female sexual hormone (progynon). With senile or prematurely old male rats, regular subcutaneous injection of progynon has the same effects as with the females: growth of hair on bald or thin regions and increase of the contents of hæmoglobin and red corpuscles in the blood.

Popularisation and Archæology

A REFERENCE to the widespread interest among the general public in the results of research in the past history of mankind has become almost a commonplace of comment on archæological matters; but few go on to inquire why such an interest should be so marked at the present day, in contrast with, say, the period preceding the War, when, for example, Sir Arthur Evans was engaged in his epoch-making investigations in Minoan Crete. To say that excavations at Ur, in Egypt, or Palestine have had a better Press in the last ten or twelve years than was given to archæology in the ten years before the War, merely begs the question. The popular Press, to which this diagnosis applies particularly, is, in this matter, a symptom of its readers' tastes rather than the cause. It follows rather than guides; but in a mistaken judgment on the situation it is prone to a sensationalism that is superfluous, in so far as its object is to stimulate an interest which already is anxious to be informed.

Actually, it is not the sensational but the familiar combined with the remote in the study of prehistory that in the long run captures the imagination of the plain man. A flint implement, be it five or fifty thousand years old, means no more to him than a useless lump of stone. Everyone, however, at some time in his life has handled a knife, a chisel, or a saw, and when the purpose of the flint implement has been explained to him, or better, when he has handled it for himself, he realises the nature of the problems which confronted his remote ancestors, and the differences in the means at his disposal for dealing with the same or similar problems. In other words, he has grasped perspective in the growth of civilisation, and also its continuity. Henceforth his attitude to the past will have undergone a fundamental change: his interest has been permanently aroused.

If it has been that in the development of archæological studies since the War attention has been directed more particularly to the interpretation of the results of excavation in terms of affiliation, to tracing the movements of races and cultures, inferring racial and cultural contacts and marking consequences in the modification or development of material culture, it is equally true that a more intense application of the results of the sister studies of geology and geography to the problems of archæology—in itself no new thing—also has produced developments which have been of the

first order of importance in stimulating research in the field and in the co-operative elaboration of theory.

The distribution map has long been a familiar implement of the archæologist's laboratory. Expertly interpreted, it has been made to tell the story of trade route and racial movement; but interpreted in the light of geology and geography, it becomes more eloquent still. Dr. Randall-MacIver, in his recent presidential address to the Section of Anthropology of the British Association, discussed the results of recent research on these lines in narrowing down the limits of search for a man's earliest ancestors and in the interpretation of the distribution of the earlier products of human industry. Even more fruitful have been Dr. Cyril Fox's researches in demonstrating how geology, geography, and palæobotany can in combination answer the questions posed by the archæological succession in showing how it came about that certain events fell out where they did, and why development should have taken certain lines. The methods of his book, "The Archæology of the Cambridge Region" (Cambridge, 1923), were demonstrated on the broader canvas of Britain as a whole in his lecture before the recent International Congress of Prehistoric Sciences (see NATURE, Aug. 13, p. 247), when he showed how two distinct geographical areas in Britain reacted differently to intrusive culture, and traced the development of the Briton from uncivilised to civilised with the gradually acquired control of his environment, as shown by the movement of settlement from one type of land to another, and followed the transfer of trade from the line Solent–Salisbury Plain to the Thames basin.

Archæological investigation on this scale is essentially a matter of synthesis of the observations of a number of individuals. It is interesting to note how archæological investigation has been assisted since the War by two Government departments acting in concert and on a scale that would have been a practical impossibility for private effort—in one instance more or less unofficially as a by-product of official activities, in the other as a part of official duties. These departments are the War Office, of which the course of training for the Royal Air Force has afforded opportunities for archæological observation and photography, and the Ordnance Survey, which now carries on its establishment an Archæological Officer.

No single recent development in archæological method has attracted so much public attention as the discovery that it is possible to discern from the air archæological remains of which the presence cannot be detected on the ground. Of the many ancient monuments and remains of which knowledge is due to this method of observation, Woodhenge in Wiltshire is the most important and the most interesting; but the utility of air observation is far from ending there, and the magnificent panoramic series of views of Wansdyke shown at the recent exhibition, illustrative of British archæology in the field, at the London Museum (see NATURE, Aug. 6, p. 196) demonstrated its value not only as a means of record, but also as an aid in the preparation of accurate plans and maps. Those who became familiar with the use of air photographs during the War will appreciate the value of this method of study in arriving at the purpose and plan of earthworks and other forms of enclosure.

The work of the Ordnance Survey has for long been concerned with the record of ancient monuments as part of its normal duties. Indeed, the Survey preserves at its office at Southampton a proof sheet of the original one-inch map of Wiltshire, made more than a century ago, which bears the manuscript archæological corrections of Sir Richard Colt Hoare. Since the first appointment of an Archæological Officer thirteen years ago, its activities in this direction have been much extended, especially in adding to the list of known monuments, both under- and over-ground. More widely known, though still perhaps less than it deserves, is the excellent series of archæological studies of which the first was the map of Roman Britain issued in 1922, Mr. O. G. S. Crawford's "Archæology from the Air" coming later, and the latest addition being the "Map of Neolithic Wessex",* an adaptation of the Quarter-Inch Ordnance Map, Sheet 11, to show the distribution of the long barrows, circles, habitation sites, and flint mines, preceded by thirty-five pages of commentary and schedules of monuments.

Without entering into a discussion of technical detail, it may be said that the interest of the Wessex map, from the point of view of its general educational value, lies in the combination of archæological, geographical, and geological detail, which shows the monuments as they lie in relation to the natural environment of the neolithic period, and at the same time invites contrast and comparison with conditions as they are to-day. A glance at the map as a whole, keeping in view geological formation, shows why settlement was in the main confined to

* Map of Neolithic Wessex. By Ordnance Survey. Southampton, 1932. 4s. net.

certain open spaces. Neolithic man avoided the forest areas, as here reconstructed, and the open heaths, in favour of the broad shallow valleys of the downs, where there were perennial streams, pasture for his sheep, and land suitable for crude cultivation. Here, too, in waterlogged clays and the narrowed strips of forest and their relation to settlement may be seen why communications followed certain lines, while along others traffic was delayed until Roman or even medieval times.

In the compilation of the map of Wessex, the Ordnance Survey was assisted by a body of voluntary helpers. Archæology is at present fortunate in having at its disposal a number of highly skilled unpaid workers; but even so, archæological field-work is normally an expensive undertaking. In these days of economic stress, expenditure which depends for its funds upon assistance from public subscription must justify itself by its works and not by faith. Enough has been said to support the view that the exposition of the results of archæological research to be popular need be neither unscientific nor sensational. An archæology that can continue to stimulate the interest of the general public in the past history of mankind need have no fear for the future and is fully justified of its children.

Philosophy Looks at Science

(1) *Philosophy of the Sciences: or the Relations between the Departments of Knowledge.* By the Rev. F. R. Tennant. Pp. ix + 191. (Cambridge: At the University Press, 1932.) 6*s*. net.

(2) *Philosophical Aspects of Modern Science.* By C. E. M. Joad. Pp. 344. (London: George Allen and Unwin, Ltd., 1932.) 10*s*. 6*d*. net.

(3) *The Approach to Philosophy.* By J. F. Wolfenden. Pp. 236. (London: Edward Arnold and Co., 1932.) 7*s*. 6*d*. net.

MANY criticisms of modern science and of scientific workers to-day relate to their excessive specialisation and the defective sense of values which specialisation is apt to engender. The philosophic views expounded in these three books illuminate the underlying causes of such defects and are of further interest from the picture they give of science as viewed and appraised by the philosophers.

(1) In the "Philosophy of the Sciences" the relations between the departments of knowledge are discussed and attention is directed to various dangers attending specialisation or, as Dr. Tennant terms it, "departmentalism". The one aspect of the facts on which the specialist concentrates is sometimes treated as if it were the only aspect, and again, disparities or discontinuities are assumed where knowledge of other fields would indicate continuity or compatibility. This danger is the more serious when experts in one sphere of knowledge make incursions into other spheres in which they are not equally at home, and thus are apt to propagate erroneous beliefs. Dr. Tennant has obviously in mind mathematical and physical exponents of the theory of relativity, whose theories are criticised in detail from a similar point of view by Mr. Joad.

Dr. Tennant observes wisely that "the history of science forewarns us, and the philosophy of the sciences can forearm us, against confounding utility for the purpose of an abstract and special science with significance for the interpretation of knowledge in its comprehensiveness, as to the world, in its concreteness". Accordingly, Dr. Tennant argues for a philosophy of the sciences which shall be able to undertake this task of mediation. By a philosophy of the sciences we are to understand not a science of the sciences, as suggested by Spencer, or a classification of them according to their subject matter, or even a comprehensive survey attempting to sum their generalisations, but a sifting of the methods and products of the special sciences which will enable us to grasp the main features of the world and to relate them as parts of one whole. The resultant systematic arrangement of the sciences according to their dependence one on another is what the author understands by a philosophy of the sciences.

Essentially, therefore, we have in Dr. Tennant's book an attempt to capture real values, the absence of which has doubtless much to do with the present chaotic condition of the world under the impact of applied physical science. To this defect Dr. Tennant obviously refers when he reminds us that "between science and the world stands human nature. . . . The world is knowable only to an extent determined by the range of human faculties and only in a manner that is conditioned by their distinctively human nature." From this we are led to the somewhat unorthodox view—which, however, is supported by Dr. Charles Singer's address to the second International Congress of the History of Science and Technology last year—that history, in the wider sense, takes the first place in the systematic order of the departments of knowledge dealing with what is known, as distinct from our knowing, its matter determining all the other sciences, and it also

prescribes the method which philosophy, as distinct from a pure science, must follow.

In support of this view, it is urged that all sciences begin with the historical and empirical facts as they are constituted at the level of philosophical organisation denoted by common sense, and that philosophy, which aims at seeing things whole and as a whole, cannot take its departure from sciences which owe their very existence to leaving out much of the stuff of knowledge because it is not scientifically manageable by them or is irrelevant to their business. The relation of history to science is discussed, and the claims of history to be a department of knowledge, although it is not an experimental science, are based on its being more than a mere inventory of items of fact; for it involves a critical sifting of its primary data, and the process of selection with which historical research passes into historiography is parallel with processes which occur in natural sciences in evolution and survival of individual hypotheses or theories.

Psychology, theory of knowledge, and history indeed reveal the presuppositions of physical science and set the bounds to its scope and functions, and only when its relations to them are appreciated can the true nature of scientific knowledge be appreciated. Dr. Tennant carries his arguments further and discusses the broad differences between theology and science, claiming that once it is recognised that all knowledge of the actual world is pre-eminently interpretative, the concepts and categories required by the historical sciences can be involved with as much right as the fewer and more formal categories by the pure sciences.

(2) Mr. Joad's discussion of philosophical aspects of modern science is more from a metaphysical point of view, but his criticism of the theories of modern physicists, although more detailed, is in general similar to Dr. Tennant's and leads him to a point of view not dissimilar. The conceptions of the physical universe sponsored by modern science are changing with extreme rapidity but are all extremely remote from the world of common sense, so that the question of their real status and other strictly philosophical questions arise. It is the business of philosophy to correlate the evidence collected by the special sciences and to try to fit it into a coherent scheme of the universe as a whole. Moreover, the vision of the artist, the religious consciousness of the saint, and the day-to-day experience of the plain man are equally facts of which philosophy must take cognisance. This urgent task of correlation and humanisation demanded by the changing conceptions of modern physics is not made easier by the increasing disposition of men of science to enter the domain of philosophy, and Mr. Joad reviews in detail the views of Eddington, Jeans, and Bertrand Russell in relation to a theory of scientific knowledge which forms the main part of the book. The philosophies of the universe based upon the interpretation of modern physics are open to objection because they regard the familiar world of sense experience as not objectively real but in some sense a product of the observer's mind. Similarly, they regard the world of modern physics as not objectively real but in some sense a product of the scientific worker's reading; and they despise brute collections of given fact and seek to analyse them away into mind or law. Starting from certain premises—what the plain man perceives and what science has discussed—they reach conclusions which suggest that the premises are misleading, in the sense that the plain man does not perceive what he thinks he perceives, and the discoveries which science has made do not truly represent the nature of what is.

These mistakes, Mr. Joad suggests, arise not from false science but from a false theory of knowledge, and he considers that eminent men of science misconceive the nature of the act of knowing and the nature of its relation to the object known. The most important part of the book is, however, not its attempt to clear up the muddle of the relation of the world of science and of common sense, but its discussion of the question of values, including the moral, æsthetic, and religious values. Religion and science are each a legitimate avenue for the exploration of reality, but of different orders of reality, and in Mr. Joad's view the researches of the scientific worker equally with the perceptions of the plain man, the moral consciousness of the good man, the sensitivity of the artist, and the religious experience of the mystic are revelatory of reality. Philosophy in its endeavour to understand every aspect of the universe is thus both a bar to which the various methods of obtaining information about the universe may be called to give an account of themselves, and also a clearing-house in which different forms of experience may be pooled. Mr. Joad's sympathetic treatment of science lends the greater force to his criticisms and exposition of the limitations of scientific method, and he wisely reminds us: "Science is still a new thing and man is still inapt in its use".

(3) Mr. Wolfenden writes an eminently readable introduction to philosophy, in which its relation to science is discussed in a vein very similar to that

of Dr. Tennant and Mr. Joad. There is very little attempt to make a personal contribution to a solution of the problems which vex mankind, but this rapid and concise review of the territory of philosophy should be of real assistance to scientific workers who are anxious to gain a sense of the value and position of science and its methods. Without such perspective, science can never take its natural place as part of the life of either the individual or of the nation, and the absence of effort to attain that perspective is commonly due at least as much to mental laziness as to the erroneous assumption frequently made by scientific workers, that the scientific method is the only way of finding out anything about anything and necessarily opposed to any other method or direction of inquiry. In addition to differentiating carefully between science and philosophy and their respective methods, Mr. Wolfenden makes a bold claim for philosophy as constructive.

Internal Combustion Engines

(1) *Internal Combustion Engines.* By Prof. J. A. Polson. Pp. vii + 475. (New York: John Wiley and Sons, Inc.; London: Chapman and Hall, Ltd., 1931.) 25*s*. net.

(2) *Automobile Engines in Theory, Design, Construction, Operation, Testing and Maintenance.* By Arthur W. Judge. (Motor Manuals: a Series for all Motor Owners and Users, Vol. 1.) Second and revised edition. Pp. 220. (London: Chapman and Hall, Ltd., 1931.) 4*s*. net.

(3) *Principles and Problems of Aircraft Engines.* By Minor M. Farleigh. Pp. xi + 277. (New York: John Wiley and Sons, Inc.; London: Chapman and Hall, Ltd., 1931.) 15*s*. net.

(4) *Heavy-Oil Engines of Akroyd Type: being Developments of Compression-ignition Oil Engines, including Modern Applications to Land Purposes, Marine and Airship Propulsion, and Railway Traction.* By Prof. William Robinson. Pp. xv + 142 + 16 plates. (London, Glasgow and Bombay: Blackie and Son, Ltd., 1931.) 7*s*. 6*d*. net.

A CENTURY ago there were neither gas nor oil engines; to-day they are counted by the tens of millions. Indispensable for the navigation of the air, the internal combustion engine has effected a revolution in road transport, it has successfully challenged the supremacy of the steam engine at sea, it has found its way on to the railroads, and it has for many years been a valuable ally of the steam engine and the water engine for the production of power for public and industrial use. In these circumstances, it is not surprising that the literature dealing with it is becoming very extensive, and that books are written regarding it, for many purposes and to suit many needs.

(1) One class of such books is represented by Prof. Polson's textbook, written for engineering students who know something about thermodynamics and the construction of internal combustion engines, but who stand in need of a general treatise on the theory and practice of this branch of engineering. There are chapters on the thermodynamics of the Otto and Diesel cycles, gaseous fuels, blast furnace gas engines, engines for motor cars, aeroplanes, ships, and power houses, and on the various appurtenances of such engines. The engines dealt with are mainly of American manufacture, and the book includes a chapter on the testing of internal combustion engines with the code of the American Society of Mechanical Engineers.

(2) and (3) Of an entirely different character are the books of Mr. A. W. Judge and Mr. M. M. Farleigh. In these there are no mathematics and little thermodynamics, but a great deal suitable for those who have to run and maintain the engines of motor cars and aeroplanes. After chapters on the combustion process and the petrol engine, Mr. Judge deals with types, lubrication, cooling, testing, maintenance, and timing of automobile engines of British make; and there is no owner or driver of a motor car who will fail to find something of interest or value in what he says.

Mr. Farleigh's book is written in non-technical form, so far as the subject allows, and is primarily intended for the licensed mechanic, the licensed pilot, the operator, and the student who desires to qualify as a mechanic or pilot. One informative chapter is that on "Trouble Shooting". Men for such work, he says, must be "men of keen intellect, imaginative, resourceful, enthusiastic, and above all wholly conscious of the importance of their work". His list of "unusual troubles" is evidence of the importance of small things, while his "cases" show how difficult it is even for experienced men to diagnose the trouble quickly.

(4) The fourth of these volumes under notice, we imagine, has been written with a desire to see that full credit is given to an inventor, Herbert Akroyd Stuart, whose name should be as familiar as that of Diesel. Stuart was born in 1864 and died in 1927; Diesel was born in 1858 and died in 1913. Their pioneering work on oil engines was contemporary but independent. The engineering world has made

great use of the work of both, and practically all heavy-oil engines of to-day are descendants of the original Stuart or Diesel engines. Both were compression-ignition engines and in both engines the oil fuel was injected into the cylinder in a spray, but whereas Diesel for this purpose used highly compressed air, Stuart used 'airless-injection' as it has now been termed. Most modern oil engines use airless-injection. Not a little confusion has been caused by the Stuart engine being called an Akroyd engine, the only instance, we are aware of, of an inventor's Christian name and not his surname being given to his invention. Many engineers are fully conversant with Stuart's work, but others are not, and in the index to Prof. Polson's book is found neither the name Stuart nor Akroyd.

Stuart's work should certainly be known to American students, for the Hornsby-Akroyd engine was introduced into the United States so early as 1893, at a time when the Diesel engine was still being experimented with in the shops of the Maschinenfabrik Augsburg, Nürnberg (now known as "M.A.N."), and of Messrs. Krupp. Prof. Robinson knew Stuart intimately, and his book is not only an up-to-date review of heavy-oil engines of Akroyd type, but also an authoritative history of the subject.

Magnetism and Quantum Mechanics

The Theory of Electric and Magnetic Susceptibilities. By Prof. J. H. Van Vleck. (The International Series of Monographs on Physics.) Pp. xii + 384. (Oxford: Clarendon Press; London: Oxford University Press, 1932.) 30*s*. net.

THE development of a scientific theory involves the interplay of observation, reasoning, and imagination. Experimental results are co-ordinated by generalisations of ever-widening scope through those imaginative leaps which place scientific method, as a whole, outside the scope of strict logic. The generalisations can then be regarded as premises on which may be built a deductive scheme, in which logical consistency is of paramount importance—logical consistency, in theoretical physics, appearing as mathematical rigour. The reasoning, however, is barren, scientifically, unless the deductions are confronted, as 'predictions', with experimental findings. If there is continued agreement, the premises take rank as a scientific theory.

Quantum mechanics, though it may not yet have reached its final form, has developed quite normally along these lines. The experimental findings with which it has been most prominently associated, both in its quasi-inductive and deductive aspects, have been those in the field of spectroscopy. Phenomena other than the purely spectroscopic, however, played an important part in the building up of the theory; and now that general postulates have been reached the range of application of which in connexion with spectroscopy has been amply demonstrated, interest centres in the development of their consequences for application in other fields. "A theory is most 'physical'", Van Vleck observes, "when it permits the calculation of a large number of experimentally observable quantities in terms of a few fundamental postulates", and this point of view characterises his presentation of the central theme of his book—the quantum-mechanical theory of magnetic and electric susceptibilities.

The book opens with four chapters dealing with classical theory. An admirable discussion is given of the relation between the macroscopic and microscopic field equations; the Lagrangian and Hamiltonian functions appropriate when electric and magnetic fields are present are derived; and the relevant results of statistical mechanics are outlined. These preliminaries lead up to the classical derivation of the Langevin-Debye formula for susceptibility due to polar molecules. The experimental results on dielectric constants and refractive indices are considered in a well-documented chapter with reference to the determination of the permanent and induced molecular moments. The analysis of these results on a classical theory basis is justified because the new quantum mechanics restores the validity of many of the classical results for electric susceptibility. The Langevin theory of magnetic susceptibility, however, rests on the classically unjustifiable assumption of molecules having 'permanent' magnetic moments, and a rigorous application of classical principles leads to the prediction of zero susceptibility, a result which is clearly explained. The difficulties and inadequacies of the old quantum theory of magnetic susceptibility are then discussed.

Quantum mechanical theory, including the perturbation 'machinery', is developed with all necessary detail, particular attention being paid to the relation between the wave and matrix methods, a combination of which, in Van Vleck's hands, has proved a powerful weapon in dealing with the problems under consideration. Application is made to the dielectric constants and diamagnetic susceptibilities of atoms and ions, the paramagnetism of free atoms and rare earth ions, the para- and diamagnetism of free molecules, and the para-

magnetism of solids, particularly salts of the iron group. Heisenberg's theory of ferromagnetism is then discussed, and also the theory of the magnetic effects of 'free' electrons. Finally, a brief summary is given of related optical phenomena.

The mathematical difficulties which arise when the attempt is made to obtain numerical results, other than the roughest approximations, from the application of quantum mechanical theory even to relatively simple systems, is well known. Van Vleck's treatment is characterised by the boldness and thoroughness with which these difficulties have been met. This is particularly marked in his own considerable contributions to the subject—as in connexion with the temperature dependence of the susceptibility of nitric oxide, with the paramagnetism of the rare earth ions (which cleared up in a most satisfying manner the discrepancies between the experimental values and those given by the approximate theory), and with the susceptibility of hydrogen. The theory of the magnetic, and also electric, susceptibilities of media which can be treated as consisting of free atoms, ions, or molecules can now be presented as a consistent, rounded whole.

For more extended application to solids generally, it is necessary to consider the effect of interactions, of which one type is the 'interchange' interaction of Heisenberg's theory of ferromagnetism. A further considerable advance has been made by Van Vleck in showing that, owing to interatomic forces, there may be a partial or complete 'quenching' of the orbital moment effect, this giving theoretical justification to a previously suggested explanation of the peculiar paramagnetic characteristics of salts of the iron group.

Van Vleck's book, owing to the inherent difficulties of the subject matter, will not be found easy reading, especially by non-mathematical readers. Its peculiar value lies in the skill and completeness with which details are filled in; it is admirably lucid, and the reader is, as it were, carried on by Van Vleck's own enthusiasm for clearing up minor as well as major points. The footnote references are numerous, and work other than that of the author receives adequate discussion. There is throughout a welcome absence of dogmatism and of that suggestion of finality which is often so irritatingly conveyed in theoretical works; moreover, excellent reviews are given of experimental results. The book is a most valuable contribution to the study of magnetic and electric susceptibilities and to quantum mechanical theory.

E. C. S.

Applied Statistics

(1) *The Methods of Statistics: an Introduction mainly for Workers in the Biological Sciences.* By L. H. C. Tippett. Pp. 222. (London: Williams and Norgate, Ltd., 1931.) 15*s.* net.

(2) *The Combination of Observations.* By David Brunt. Second edition. Pp. x + 239. (Cambridge: At the University Press, 1931.) 12*s.* 6*d.* net.

STATISTICS is a subject which has grown very rapidly during the last twenty years, and it is therefore inevitable that the textbook should tend to depart more and more from the traditional form. The emphasis has somewhat changed, and the need to-day is to cater for the growing public that desires to know something of the practical tests that may be applied to the numerical results of experimental work, in which the sample is not usually very large. In particular, the present-day biological worker is characterised by a thirst for knowledge of the *results* of statistical research, combined with a stoical indifference to the mathematics used to bring about these results. The sampling problems that serve as a basis for the practical tests are of some mathematical difficulty; nevertheless, they are of fundamental importance, and the ideas tend to be introduced at a much earlier stage than has hitherto been customary. If the reader is prepared to take the mathematics on trust, then certainly the tests he is asked to carry out, generally with the aid of tables, are not difficult.

(1) The pioneer textbook in the new form was R. A. Fisher's "Statistical Methods for Research Workers", in which not only was much new matter introduced to the consideration of teacher and student, but the method of presentation was also radically altered. Where difficulty has occurred, it has usually been due to an inability on the part of the reader to appreciate the subtleties of the argument, through ignorance of the theory on which it is based. On the whole, however, the biological worker is getting what he wants, and Tippett's "Methods of Statistics" is to be welcomed as another manual of statistics in the new style, which, within the compass of a little more than two hundred pages, covers a very great deal of ground.

There is little in the way of practical tests that does not find a place, and the book will repay careful reading. The numerous examples are welcome, but could with advantage have been treated in greater detail, at any rate at the

beginning; unless the reader fully understands the nature of every step in the calculation, which should be made clear by the actual working, and not solely by reference to formulæ, he is liable to be brought to a full stop. In fact, a general criticism is that the cloven hoof of the mathematician is occasionally allowed to obtrude itself, and the reader, while spared the proofs of the formulæ, is nevertheless assumed to be an adept at the equally difficult (to him) question of mathematical symbolism.

We welcome the further attempt to standardise a satisfactory notation, but terms are used which are still novel, and it is all the more necessary, therefore, to define them precisely, and avoid through looseness of statement any suggestion of giving a different shade of meaning to words already in use. In particular, the ideas of *population* and *sample*, and the distinction between population parameters and the estimates of these derived from a sample, have so recently emerged from an obscurity that was often deepened by the use of an insufficiently distinctive notation that the greatest care is necessary in elaborating these ideas.

(2) Mr. Brunt's book, the first edition of which appeared in 1917, is of a more heterogeneous character. It is described in the preface as a manual of least squares. The theory of errors of observations is developed along standard lines, and the details of the adjustment of observations by the method of least squares is very full. In a series of supplementary chapters, which alone have been revised in the new edition, some attempt is made on one hand to amplify the earlier treatment of the theory of error for the benefit of the biometrical worker, the subjects chosen being alternatives to the normal law of errors and correlation; on the other hand, an excellent account is given of harmonic analysis and the periodogram.

In contrast to Tippett, the book appeals to the mathematical reader, although in actual fact the mathematics is never very profound. The heterogeneity, evident from a description of the contents, is emphasised by an unfortunate change of notation when passing from the theory of error proper to the studies more appropriate to the biometrician, and by the separation of the chapters on least squares from the study of multiple correlation, when the latter, in fact, follows naturally from the former.

It may be doubted whether it is desirable in a book of the size and character of this to enter into details of the fitting of the Pearsonian or other forms of frequency curves. A general idea only of this development can be given, and the practical details of fitting are not entered into. While it is desirable to point out that not all populations are normal in character, it is also true to say that few experimenters have data so ample that significant departure from normality is found to exist. It is thus possible to find a self-contained textbook like that of Tippett in which the assumption of normality is implicit throughout. Brunt's textbook cannot claim to be a manual of statistics; at the best, only selected portions of the subject are dealt with, and the book as a whole is of a character that must be becoming increasingly difficult to write in this age of specialisation.

The early examples on the reduction of observations would have been improved by a discussion of tests of goodness of fit, while the chapter on correlation deals rather lamely, for a book of a mathematical character, with the formulæ for the probable errors of the various constants, which are introduced without proofs and with no discussion of their limited applicability in general to problems of this kind. The book is, however, clearly written throughout and there is little in it that is obscure. It should continue to be of service to the class of student to whom it is addressed.

J. Wishart.

Short Reviews

An Introduction to Organic Chemistry. By Prof. R. J. Williams. Second edition. Pp. xi + 585. (London: Chapman and Hall, Ltd., 1932.) 21*s.* net.

The publication of a second edition of this book four years after its first appearance, coupled with the fact that during those four years it was reprinted four times, is eloquent testimony to its popularity among both teachers and students of organic chemistry. This success must be attributed to the manner in which the author has presented most of the material, the result being a connected and well-written story in which many of the more recent advances of knowledge are incorporated.

In the main, the scope of the work conforms to its title, but the book differs from many of the smaller books on general organic chemistry in that considerable space is devoted to electronic formulæ and to a discussion on the structure of benzene. The predominant and most commendable features, however, are the lucid explanations of reactions and an array of graphic formulæ in support of the verbal explanations. At the same time the book stimulates thought, and the resourcefulness of the student in applying his knowledge is put to the test at the end of each chapter by means of a judicious selection of problems.

In general, the treatment is adequate, sound, and

up to date, but the section on heterocyclic compounds, including the chapter on alkaloids, must be amplified in a future edition if it is to satisfy the requirements of many of those students for whom the book has been written.

Le soleil. Par Prof. G. Bruhat. (Nouvelle Collection scientifique.) Pp. xii + 240 + 16 planches. (Paris : Félix Alcan, 1931.) 20 francs.

PROF. BRUHAT has used a course of lectures given at the Sorbonne in 1930 as the basis of this book, but has eliminated to a great extent the mathematical treatment of his subject in order to reach a wider circle of readers. All who possess an elementary knowledge of physical sciences will find the book an interesting, clear, and up-to-date account of the present state of our knowledge of the sun, as well as of the instruments and methods used in attaining that knowledge. A considerable amount of this matter is not to be found in any English works of a similar nature, but the historical accounts are occasionally inadequate or even definitely misleading.

Problems concerning the internal constitution of the sun or its evolutionary history receive little or no attention, as being beyond the scope of the book ; apart from this, however, recent advances in observational methods, results, and theories form a prominent feature, and the whole supplies a good introduction to modern solar physics. The printing and paper leave much to be desired, and an index would have been a useful addition to the book. The plates are suitably chosen as representative of the subject matter and well reproduced ; they are bound together at the end, and consist mainly of photographs taken at the Meudon Observatory.

A Manual of Determinative Mineralogy, with Tables : for the Determination of Minerals by means of 1. Their Physical Characters ; 2. Blowpipe and Chemical Properties ; 3. Optical Properties. By J. Volney Lewis. Fourth edition, revised by Prof. A. C. Hawkins. Pp. ix + 230. (New York : John Wiley and Sons, Inc. ; London : Chapman and Hall, Ltd., 1931.) 18*s*. net.

WITH the exception of certain minor alterations, the fourth edition of Prof. Lewis's well-known "Manual" differs but little from the third edition published in 1921. Prof. Hawkins, in his revision, has effected a very considerable saving in space, amounting to 68 pages, mainly in the physical tables. Instead of repetition in the case of such minerals as fall into two classes, an effective system of cross references has been employed. Further, in the tables of blowpipe reactions, certain rare and relatively unimportant species such as jarosite, glaucodot, etc., have been eliminated.

A short section has been added on optical properties, mainly with the object of impressing on the student the importance of optical properties in the determination of minerals. Optical data are given for a few common minerals. In its revised form, this work remains an exceedingly useful and simple guide to the determination of minerals according to their physical properties and blowpipe reactions.

Divorce : a Social Interpretation. By Prof. J. P. Lichtenberger. (Whittelsey House Publication.) Pp. xii + 472. (New York : McGraw-Hill Book Co., Inc. ; London : McGraw-Hill Publishing Co., Ltd., 1931.) 21*s*. net.

THE use of scientific method and the disuse of appeals to authority, whether ecclesiastical or other, are the leading characteristics of this book. The author first states the problem, which is the explanation, not the justification, of the present divorce situation. He then enters upon a historical and descriptive account of marriage and divorce from the earliest to modern times, with special reference to America. Then, after considering some explanations of the divorce 'trend' which he regards as inadequate, he proceeds to develop his own lines of explanation. We think he begins badly by laying it down as an axiom that "divorce is an effect, not a cause", since the disintegration of the marriage has taken place before the divorce. But easy divorce is surely one cause of light views of marriage, and therefore of easy virtue. Yet there is so much excellent material in the book that it must be accounted a serious contribution. The author's wide knowledge of the literature of the subject makes him extremely apt in quotation.

A Naturalist in Brazil : the Flora and Fauna and the People of Brazil. By Prof. K. Guenther. Translated by Bernard Miall. Pp. 400 + 32 plates. (London : George Allen and Unwin, Ltd., 1931.) 25*s*. net.

THIS is an admirably illustrated book on the flora and fauna of Brazil. It marshals the natural history of the country in an instructive manner, but we do not discover that the author has concentrated on any special problem or added much to our previous knowledge. His chapters on "The Mosaic of Colours" and "The Symphony of Voices" are attractive, while the variety of devices employed by parents for ensuring the survival of their young will attract many readers. This is a book invaluable to anyone who desires to visualise the country and its inhabitants, a pleasant 'Baedeker' of Nature.

The Sciences of Man in the Making : an Orientation Book. By Edwin A. Kirkpatrick. (International Library of Psychology, Philosophy and Scientific Method.) Pp. xv + 396. (London : Kegan Paul and Co., Ltd., 1932.) 15*s*. net.

IN the short compass of this volume, the author surveys the various sciences referring to man, from anthropology and ethnology to economics and politics, and from psychology to morals. No particular views are expressed, which belongs to the 'orientation' type now so popular in the United States. The 'suggested readings' at the end of each chapter refer almost entirely to American publications and authors. As a restatement of questions of methods relating to the study of mankind, however, the book makes enjoyable reading. T. G.

The Growing Tree *

By Prof. J. H. PRIESTLEY

RECENT studies of the growth of the tree, helped by some new methods, have shown that each season this growth begins in the bud, whence it spreads downwards over the rest of the tree. The discovery of this fact may influence, in quite a surprising way, our understanding of the tree—its form, its structure, and its vital functions.

LONGITUDINAL AND RADIAL GROWTH

The plants we call trees clearly have certain characteristics in common, though the botanist does not group them together in one class. They produce new crops of leaves periodically, but usually they do not flower for a number of years. Green leaves add to the substance of a plant, whilst flower and fruit exhaust it, so that the tree continues to gain in size and weight for many years. Much of this added weight is wood and bast, of which new increments are added each year, on the outer surface of the wood and the inner surface of the bast, by the activities of a growing tissue lying between wood and bast, called the cambium.

Each new crop of leaves is not borne directly upon the old wood but on new shoots which emerge from the buds. These new shoots grow in length, whilst the old branch system thickens but grows no more in length. The two growth processes do not seem connected at first sight, but the tree will only be understood when we realise that they depend very closely upon one another. During this year a new method of studying radial growth has been developed by which it has been possible to show how closely extension growth and radial growth are connected.

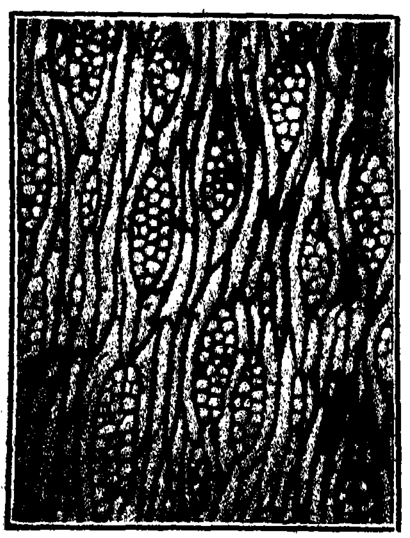

FIG. 1.—Photomicrograph of a strip of new tissue scraped from the surface of the old wood in ash. These cells have been formed by division of the cambial cells. × 100.

When the cambium recommences growth, its cells become very liquid, and the bark together with the bast easily peels from the wood, or, as we say, the bark 'slips'. The new soft plastic tissues can then be scraped off the hard old wood surface with a sharp tool, and long strips of tissues, newly formed from the cambium, can be obtained with the utmost ease. It has thus been possible to show that these tissues are first formed beneath the buds as they commence to grow, and that the cambial activity spreads thence always downwards—down the branches and down the trunk. These strips of tissue, as shown in Figs. 1, 2, and 3, exhibit beautifully under the microscope the structure of the new cells just formed from the cambium, and their study should reveal many new and interesting facts as to the changes these tissues undergo as they are transformed into wood.

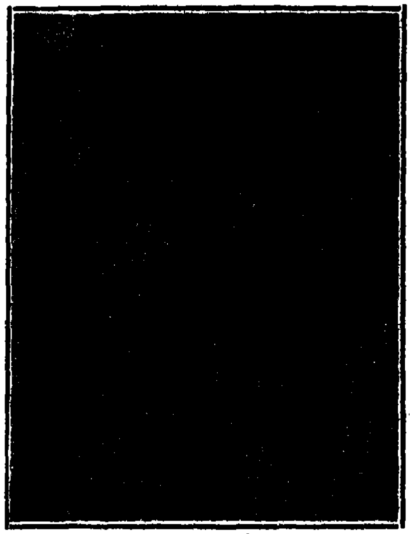

FIG. 2.—Photomicrograph of strip similar to that in Fig. 1, taken from spruce. Note the great length of the cells. × 133.

This new method has revealed most clearly the dependence of radial growth upon the buds. Cambial activity only begins after the buds commence growth, and cambium growth always spreads downwards from the base of the buds. We now know why, when pruning, the knife should cut across the stem just above a bud. Thus no piece of stem is left projecting above the topmost living bud. When such a piece of stem is left, the cambium in it never grows again, and this piece of stem withers to an unsightly snag.

The growth of buds depends very much upon light. The forester therefore plants his trees close together, so that the lower, side branches are shaded and their buds soon cease to grow. These branches then grow no more in thickness, lose their water, and become dry. On such withered branches the bark does not 'slip' but clings close, whilst on the main stem around their bases it is being pushed outwards by the growth of the cambium. The bark is thus thrust into sharp folds around the base of each withered branch, and the strain increases with continued growth until the dry branch is snapped off. Thus the lower dead branches are swept off, new wood still forms each year, and the stumps of these branches are gradually buried in the wood of the growing trunk, not to be seen again until they appear as knots in planks cut from the trunk. On the surface of the tree, the folds of bark may

* Substance of the presidential address to Section K (Botany) of the British Association at York on Sept. 5.

persist for many years, indicating the presence of these branch stumps, as the ripples on the pond tell of the stone sunk in its depths. The folds may be studied and recorded very simply, by placing paper over the bark and rubbing it with cobbler's heel-ball.

Softwood and Hardwood Trees

Branch systems, and the knots they leave in the timber, are rather different in two different tree types, the broad-leaved hardwood and the needle-leaved softwood. The former belong to the class of Dicotyledons, whilst the softwood belongs to the conifers.

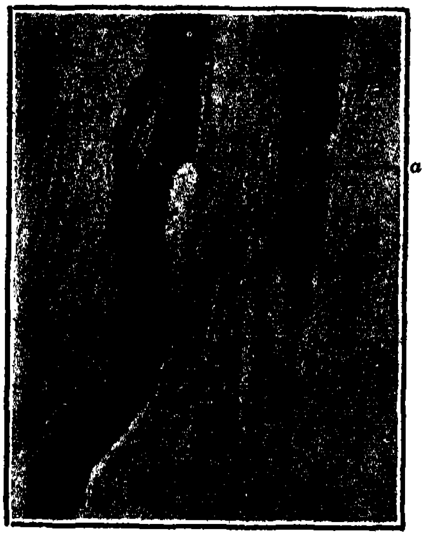

Fig. 3.—Photomicrograph of the new tissues, derived from the cambium in sycamore. Through the new tissues, are developing vessels (a) which are in communication with the leafy shoot above. ×100.

The softwoods have usually a very regular 'Christmas tree' habit of branching, a new whorl of branches appearing usually each year, and each spring as the buds begin to grow, radial growth begins and spreads downwards from the buds, but the lower and more shaded the branch, the slower the radial growth activity spreads down it. As a result, the cambium is growing actively on the main trunk, around the bases of the lower branches, before growth has begun on the branch bases themselves. The old wood of the branch is thus gripped in the new wood of the trunk which forms around it but is not in actual union with it. Only later, as the cambium on the branch also begins to grow, do branch and main axis join in forming one common sheet of wood. In a thin softwood plank, therefore, the wood of the branch may lie loose in the wood of the trunk and, if the wood of the main stem rots away, the tapering ends of the whorl of branches may often be seen projecting inwards into the hollow trunk (Fig. 4).

In the hardwood, branches do not arise in so regular a manner, or so many at one level, but when growth begins, the branch base and the main axis at the same level commence growth at almost the same time. Main stems and branch therefore join in forming a common layer of wood from the outset, and thus the knot, even in a thin plank, will be firm. This continuity of wood from the branch to the main axis is clearly shown in Fig. 4.

In both poplar and oak in Great Britain, branches that do not make good growth tend to be cut off before they wither, by a natural process of abscission (see Fig. 5). This happens especially with flowering branches of the Canadian black poplar, and each summer the ground beneath trees that have commenced to flower is carpeted with branches with smooth expanded bases which have fallen from the trees, while saucer-shaped scars are left on the branches from which they have fallen.

In the softwood, the living cells of the cambium are like very long, thin threads. Each thread grows in size and then cuts itself lengthwise into two equally thin threads, of which the inner one will in time become a new wood element, as seen in Fig. 2. In the process it will absorb much water, its wall will thicken and lignify, its living contents will disappear, and it will thus become a fibre or tracheid. All these fibres are of much the same size, a few millimetres long, and they all expand about the same amount during development, more in the early part of the season, when they form the thin-walled spring wood, less later on when they form the summer wood, so that each year's ring of wood is thus recognisable as an annual ring. As all the developing tracheids, cut off from the cambium at the same time, do the same thing, to the same extent, in about the same period of time, the wood is very regular and composed entirely of similar fibres. When these developing tissues were scraped off the old wood in June, a fine spray shot into the air to a height of more than a foot, so that the liquid in these minute developing tracheids must have been held under great pressure. It is this pressure, squeezing the soft cambium cells out against the inside of the bark, which probably

Fig. 4.—On left, a branch union in a hardwood (Large-leaf maple), showing clearly the continuity of wood from branch to main axis. In the centre (Grand fir) and on the right (Douglas fir) are cross sections of softwoods, in which the inner wood of the main stem has rotted away, leaving the tapering ends of the wood of branches projecting into the hollow cavity. The branch of the Grand fir, in the centre, was growing horizontally and has formed more wood on the lower side. (Photograph by Mr. Pemberton, British Columbia.)

accounts for their curious shape. The more vigorous the growth of the tree, the longer these thin flattened threads of cambium cells become.

In the hardwood, on the other hand, the cambium cells are much shorter, smaller cells, and cut off cells like themselves towards the wood, which later may take in water and expand. But these short cells have transverse walls at the top and the bottom, which collapse under the strain, so that the contents of the cells coalesce. This happens to certain vertical series of cells over long distances

in a very short time, so that a long row of such tiny cells expand very considerably in width and coalesce end to end to form a vessel which may be many feet in length and more than a tenth of a millimetre in diameter, as shown in Fig. 3. The formation of this vessel, like cambial activity, begins beneath the bud and spreads thence very rapidly downwards. It follows that, at lower levels, the cell which lies just in the line of such a vessel is expanding with water before its neighbours which were formed at the same time, and its expansion takes place at their expense. The vessel segment expands relatively greatly, whilst the other cells are squeezed and elongated. These longer cells, when later their walls thicken, become the fibres. Thus the hardwood, in contrast to the softwood, has a diversified wood structure, with vessels interspersed amongst elongated narrow fibres, whilst the swelling of the vessels is not accompanied by a great pressure against the cambium, the cells of which remain relatively short.

FIG. 5.—Twigs of oak, fallen whilst still living by a process of natural abscission. The swollen scars are shown clearly. About ½ natural size.

WATER SUPPLY TO OPENING BUDS

These characteristic growth processes in the tree have a direct bearing upon such a problem as the movement of water in the tree. The water enters at the roots, and great forces are needed to carry it to the tops of trees which may be more than 300 feet high. It moves in the wood, in the tracheids of the softwood or the vessels of the hardwood, and it is usually assumed to-day that it is driven upwards by forces in the root and pulled by forces at work in the leaves from which water is evaporating. But we have seen that if a bud does not grow, both the bud and the twig beneath it lose water, so that the growth of the bud seems to attract water into it. Water is necessary for the growth of the bud, and an old experiment seems to throw light upon the entry of water into the bud in spring. If a cut branch is warmed in spring, water can be seen to well from the wood at both cut ends. In the uncut branch on the tree, the same movement of water will take place as the temperature rises, but now, from the way the wood has been formed, all this water will find its way into the buds, where the ends of the most recently formed wood elements are to be found. Then the bud begins to grow, and growth spreads downwards through the cambium beneath the bud.

It can be shown that both these growth processes attract water out of the old wood by osmotic forces developed in these growing tissues. Water movement in wood can be shown to take place under the operation of such forces, and the conditions to develop such forces can be demonstrated in the developing tissues. When new wood develops beneath an expanding bud, down over the surface of the old wood, water is moved from the old wood, which thus acts as a reservoir, into a new system of pipes the terminus of which is to be found in the elongating shoot with its new leaves. It is evident that this is the way in which the new shoot obtains its water, and that this is the explanation why a branch that does not grow loses its water to the growing parts of the tree. This gives us quite a new picture of water movement in the tree, which is no longer seen as a movement along one set of pipes, either pushed from below or pulled from above in direct continuity with the new shoots.

WATER SUPPLY TO THE EXPANDED FOLIAGE

During the winter, when water still enters the roots and the shoot system is not growing, the supply of water in the old wood is increased; but immediately growth begins in spring, water is drawn from the old wood into the new tissues, and a simple type of experiment shows that it is withdrawn more quickly than it is replaced. When the wood is cut open under a coloured liquid such as Indian ink, no ink enters the newly developing vessels, which are obviously full of liquid, but it rushes into some of the old wood lying just beneath these new tissues, thus showing that their contents are in a condition of tension. In early summer, when the leaves are expanded, the ink will also enter the first formed of the new wood elements, the contents of which must also now be under tension. This experiment is most striking if carried out in June with the ash, when the long vessels lie just below the surface of the cambium and are visible to the naked eye. When they are cut open under Indian ink, the ink shoots both upwards and downwards at a rate which often exceeds 20 ft. a minute, and thus travels to a distance of many feet from the place of injection. The ink will not pass the cross walls which close the vessels at intervals, but lead nitrate will do so, and can be shown to travel in a few minutes down into the roots and up into the leafy shoots. The experiment has a very practical side, because it shows how soluble poisons may be successfully used to kill a tree. This is sometimes a real need, as in tropical Africa at present, where control of the movement of the tsetse fly is being attempted by completely clearing belts of country of vegetation.

It is usually assumed to-day that when the contents of the wood are in a tensile condition, the wood contains liquid sap at relatively high ten-

sions. This view is difficult to reconcile with the rapid entry of the injecting fluids, and the result of further injection experiments is to suggest that many wood elements in tension contain water vapour. Such elements, when water is available, will readily fill with water again. These observations do not solve the problem of the ascent of sap in tall trees, but they do suggest it is ripe for reconsideration. They also remind us that the buds and branches at a great height always obtain their water by a machinery that is only set in motion by their own growth.

Similarly it may be pointed out that the downward movement of food in the tree—a movement that is usually associated with the bast—seems to be linked with the growth of the bast. This tissue is also formed from the cambium, its formation beginning in the leaf, whence the process spreads gradually down the branches to the trunk and the roots; and the spread of this process of growth synchronises with the time at which a gain of dry weight takes place in the lower regions of the tree. If an attempt is made to estimate the amount of transfer of substance involved in the formation of the new tissues from the cambium, this downward-progressing growth process evidently largely accounts for the movement of substance that takes place. It is clearly impossible to dissociate the problem of transport in the tree from the processes of growth.

Measurements of Solar Radiation *

THE work of the Smithsonian Institution's Astrophysical Observatory during the decade 1920–30 is described in vol. 5 of its *Annals*, recently published after an interval of ten years since the appearance of the preceding volume. To assist the reader in forming a proper perspective view of the work, the volume is prefaced by a brief description of the long research on solar radiation undertaken by the Observatory, first under Langley, and later under Dr. C. G. Abbot. It forms an impressive account of a great investigation, of fundamental importance to meteorology, in which the Smithsonian Institution has been the pioneer and practically the sole worker. The latter is to be regretted, since it is desirable to have independent determinations of so important a quantity as the sun's radiation. There is fortunately no doubt, however, as to the substantial accuracy of the mean Smithsonian value of the 'solar constant'.

One decisive result has emerged from the work of the Observatory, as a consequence of gradual improvements both in the instruments and methods of observation, and in the understanding and reduction of the measurements. It is that the sun's radiation, as it reaches the outside of the earth's atmosphere, and after correction to the mean distance of the earth from the sun, *is* constant within very narrow limits. At earlier stages of the work the Smithsonian view was contrary to this; it was contended that the observations showed variability over a range often exceeding five per cent; the supposed variations ranged over several per cent in the course of years, and showed correlation with the sunspot period; there were also variations over short periods of a few days, which were believed to be confirmed by independent observations for more than fifty days at Bassour in Algeria and Mount Wilson in California. Important consequences for terrestrial weather and weather forecasting were inferred from these results.

In the present volume an account is given of the establishment and progress of several solar radiation observatories, located on mountain tops in desert lands, at which a daily record of the sun's radiation is attempted, both as received at ground level, and as inferred after allowing for atmospheric absorption. The conclusion is reached that "the earlier impression [of considerable solar variations] is not supported". "We incline to think that the earlier impressions of a larger solar variability were founded on measurements too much affected by terrestrial atmospheric influences. A residuum of apparent solar variation remains, nevertheless, after making all possible improvements. Comparison of results of remote stations; correlations with other measurements independently made by other observers; and especially correlations with weather changes at remote stations, all incline us to consider present indications of solar variation as largely real" (p. 5). The average deviation of the solar constant as measured at a single station on a single day is given (p. 244) as 0·29 per cent, the probable error being 0·24 per cent, as derived by comparing the measurements of the best station (Montezuma, Chile) with those made at Table Mountain (1926–30).

These changes are very small, and in view of the great difficulties involved in correcting accurately for atmospheric absorption, a proof of real solar variability must, as is stated, be very difficult. Comparison of the variations recorded at Montezuma and Table Mountain, in cases where satisfactory daily observations occurred consecutively at both stations simultaneously over intervals of ten days or longer, is thought, on the whole, to show a great similarity in the march of the curves, though there are instances of great dissimilarity. But it is pointed out that in these intervals solar changes exceeding 1·5 per cent are rarely indicated.

My own impression, after reflecting on the observational difficulties, the possibility of accidental agreements between the changes at different stations, and the past history of the research, is that the reality of these small variations is not proved. To establish them, much better evidence is required in the form of long-continued observations at different stations, and also independent determinations by different methods at the same station. The correlations with other measurements, and especially with weather changes, which

* Annals of the Astrophysical Observatory of the Smithsonian Institution. Vol. 5 (Pub. No. 3121). By C. G. Abbot, L. B. Aldrich, and F. E. Fowle. Pp. ix+295+11 plates. (Washington: Government Printing Office.)

are mentioned as accessory evidence in the above quotation, seem beside the point; indeed, they prompt doubts as to the soundness of the discussion and interpretation of the data, doubts which are strengthened by the description of the methods used for determining alleged periodicities in the small observed variations of the solar constant. This part of the text is taken substantially from Dr. Abbot's paper of 1931, entitled "Weather Dominated by Solar Changes", the main thesis of which has not carried conviction with most meteorologists. On this point, I am in agreement with Dr. Kimball, who, in the *Monthly Weather Review* (Dec. 1931, p. 479), wrote, "Is it rational to believe that these major weather changes are caused and explained by alleged short-period changes of less than 1 per cent on the intensity of solar radiation? A part, if not all, of this 1 per cent variation must be set off as caused by inevitable accidental errors, but even if the whole of it were real solar change, can we believe that if this small variation were to cease our major weather changes would disappear also?"

I would regret, however, to end this review on a critical note. The answer to doubts as to the solar variations will be afforded by observations which the Astrophysical Observatory is continuing, and by others for which it makes an earnest plea. While Dr. Abbot states that even the best present data, from Montezuma, fall just short of the accuracy that is required, he adds that there is good hope of making several improvements which should appreciably diminish the experimental error at all the stations.

Besides the main work relating to daily observations of the solar constant, the volume includes an account of the study of the distribution of radiation in the solar spectrum, particularly in the ultra-violet and infra-red regions not covered by the daily solar observations. One interesting and unlooked-for result of the Smithsonian work was the determination of the ozone content of the atmosphere above certain stations, from the yellow-green atmospheric transmission coefficients.

S. CHAPMAN.

A Bibliography of Boyle

'BIBLIOGRAPHY' is a word which has many meanings. The merely enumerative cataloguing of books is the least; their discrete anatomies a higher; and highest of all is their comparative anatomy, working on from detailed observation through steps of induction and verification as rigidly and delightfully scientific as any man of science could desire. But the aims of those who practise in these loftier realms are not always single. On one hand, the pure bibliographer has for his aim the discovery of bygone methods in the various crafts of book-making; to him the matter in the volumes which he studies is no more than the 'copy' supplied to a compositor, and the mind of the author—except inasmuch as its vagaries may cause disturbances in proof, and produce variant issues—exists as a remote First Cause, beyond inquiry. How much of the archæology of the greatest art in civilisation has been discovered by such students is recognised only vaguely, even by some of the historians who might make use of it. The literary bibliographer, on the other hand, has a different aim; his primary interest in a series of books is in their author (or a group of authors); yet even he wins little enough sympathy from most of us, who are content with the innocent rôle of gentle reader.

It will be seen that the bibliographer is a lonely soul as a rule; and if he strays beyond the warmth of his own circle, the wind of the world blows past him chilly and comfortless. No wonder that he and his kind have hitherto purposely shunned contact with students of the impersonal arts of Nature, who outside *their* circle are supposed to be inhumanly heedless of persons and the past, and regardful only of things and the present. There have been, nevertheless, bibliographies (in the full sense) of scientific work: usually, however, according to subjects—such as Mr. James Henderson's "Bibliotheca Taqularum Mathematicarum"—or of a library, such as Ferguson's well-known work on the Young chemical collection. Of bibliographies of single scientific authors there must hitherto have been very few that would satisfy bookmen as well as men of science. However, the collector's enthusiasm of the late Sir William Osler for medical works set a vogue in this field, and so it was not surprising that William Harvey was the subject of the first true bibliography of a seventeenth century scientific worker, produced a few years ago by Mr. G. L. Keynes. Now a kindred interest has inspired Prof. J. F. Fulton, lately fellow of Magdalen College, Oxford, and now professor in the School of Medicine at Yale, to undertake a larger and very difficult task: the bibliography of Robert Boyle.*

Let it be said at once that Prof. Fulton has carried out the task with particular success, happily conjoining the functions of both types of bibliographer. He has not only used the resources of a score or so of great libraries in Great Britain and on the Continent, but he has also achieved the rare privilege of being himself the owner of at least one copy of very nearly every work, edition, issue, and variant that comes within the wide scope of his title. The unrestricted opportunities for close examination and repeated reading which this has given him show, by their results in this volume, the honourable side of book-collecting; and the scientific historian (or, more probably, the group of them) who may some day try to set before us Boyle's contributions to knowledge, will be deeply in Prof. Fulton's debt.

In Section A are described forty-two distinct and self-contained works by Boyle, first printed between

* *Proceedings and Papers of the Oxford Bibliographical Society*, vol. 3, pt. 1, pp. 1-172. "A Bibliography of the Honourable Robert Boyle, Fellow of the Royal Society", by J. F. Fulton. (Oxford: University Press.) 10s.

1659 and 1695, and afterwards in editions and issues described to the number of about two hundred. This constitutes the most important part of the bibliography. In Section B are cited forty contributions by Boyle to other works, including thirty-five papers printed by the secretary of the Royal Society in the *Philosophical Transactions*. A third section shows the editions of Boyle's collected works, including the separate theological collections; there follow ten examples of book-dedications to him, contemporary and later; ten elegies and funeral sermons; and notices of about a hundred and seventy biographies and commentaries on Boyle. An appendix contains a list of the Boyle's Lecture sermons and their preachers from 1692 to 1929, and a list of the Robert Boyle lectures which have been given at Oxford for the last forty years. The frontispiece shows the attractive bust of Boyle by Rysbrack, discovered lately at Kensington Palace by Mrs. Esdaile; and there are twenty-two facsimile reproductions of title-pages and other matter. Prof. Fulton's preface is pleasant and useful, and there is a full index.

Each separate work is introduced by a short account of its bearing upon Boyle's life and upon the parts of science which it touches together with notes of general bibliographical interest. For each volume described, there are given the full title, with indications of the types used; the collation; any sub-title; notes of relationship to other issues; any special points; and a list of places where copies exist. As to the thoroughness of the book-anatomy, the reviewer can only say that he had a few small discoveries in this field which he thought were his own—but they are all here, and many more, and his chagrin as a censor is replaced by pleasure as a pupil. Prof. Fulton's assessments of Boyle's works do not profess to be more than finger-posts, and ultimately the hoped-for scientific historian of Boyle might here and there dissent from a judgment. But, subject to this merely occasional reflection, Prof. Fulton's prefaces really add to the worth and interest of the book.

The Oxford Bibliographical Society is to be congratulated on having produced as part of its *Proceedings* a handsome bibliography which is not only new in theme and long-wanted, but also as nearly final and complete as even, perhaps, its author could desire. To his modest terminal quotation from one of Boyle's prefaces, disclaiming the world's applause, one may be allowed to reply with one from another author; Dr. Fulton's is a work "In which, though to the blind and common crowde (to whom all thats unusuall is a paradox) there may perhapps appeare what they'll dare call extravagant, and to the midle-cyzed gymnastickes what they'll conceive ill grownded though ingenious guesses, yet surely will the more solide reflections of all knowing men begette a liking of its acquaintance". Irvine Masson.

Amalgamation of the Physical and Optical Societies

After full consideration of the scientific, legal, financial, and political questions involved, a scheme for the amalgamation of the Physical Society of London and the Optical Society has been drawn up and unanimously recommended by a Committee representative of the two Societies. The process is now complete, and a new society, the Physical Society, has come into existence.

In pressing forward the scheme to completion, the Councils of these Societies were gratified to find that they had the support of an overwhelming majority of the members of both Societies, who fully realised that, despite the grave nature of the change involved, the advantages attendant thereon completely justified the action of the Councils.

It must be understood that the scheme is, as it states, an amalgamation—a fusion of the Societies concerned. The preservation of the name of a society is a matter which has, at best, a sentimental value; the conservation and widening of the advantages of membership is the material concern. In making a balanced estimate of the advantages accruing from such a fusion, it must be remembered that the circumstances in which the Optical Society was founded are scarcely germane to the present situation. However specialised its aims may have been in the earliest years of its existence, the Optical Society, as a glance at its *Transactions* will show, has developed into a general scientific body with an outlook scarcely to be distinguished from that of the Physical Society of London.

Thirty or forty years ago, in the homely days of the Victorian era, there was room, and need, for small semi-private societies, the members of which might meet and discuss in a familiar and intimate way problems of fundamental interest in their science and profession. Matters are changed nowadays. Physical science is playing a part in the fashioning of national character and the fostering of national well-being which was undreamt of a generation ago: scientific bodies are in far closer touch with the organised activities of the community than they have ever been in the past, and unnecessary divisions and separations are to be deprecated, inasmuch as they inevitably weaken the weight of any appeal which may be made by the societies in the name of physical science. There is no question that the prestige and authority of the Society which has risen from the union of the two Societies will far exceed that of the individual Societies considered as separate units.

The amazing growth of physical science during the past generation has inevitably produced much specialism. So far from taking all knowledge for his province, the scientific man of to-day is fortunate if he can cultivate with a measure of success some one corner of one of the sciences. Nevertheless, the repercussions of physical science in general on that single division are so numerous and so important that the neglect of their study unduly hampers the serious student. It has been an important part of the business of the Physical Society of London to make possible a critical study of these repercussions; the lectures and discussions which

have been held, and the reports which have been published under its auspices, the issue of *Science Abstracts*, the fortnightly meetings in London which resulted in the reading and annual publication of some fifty papers concerned with all branches of physical science, the annual provincial meeting—all these activities have helped to provide a background for the specialist worker in physics such as could be obtained by membership of no other British society. And, as is shown by their membership of the Physical Society of London, many fellows of the Optical Society have not been slow to recognise these advantages.

In some quarters a fear has been expressed that the fusion of the two Societies will leave workers in applied optics without a forum in which to express their views. Nothing could be farther from the truth. Optical science is no longer confined to a narrow sphere of influence but has become the handmaid of all sciences, and optical instruments are now tools of industry. The amalgamation now completed is a visible sign of the union, to their mutual benefit, of the most representative body of producers of optical methods and instruments with the body which represents the largest and most important group of users of such methods and instruments. Under the auspices of the new Physical Society, the Guthrie lecture and the Thomas Young oration will be delivered as heretofore; papers on optical subjects have been a prominent feature in the *Proceedings of the Physical Society of London*, and their number will be materially increased under the new regime; arrangements for special lectures on topics of optical interest have been made, and the session now opening will be inaugurated by a lecture by Dr. J. W. French on "The Manufacture of Optical Glass"; and the probability of an increased output of papers is provided for by an increase of one part per annum in the number of published parts of the *Proceedings*.

The Councils of the Societies have no regrets in carrying out this amalgamation. They believe that it is, in brief, a plain commonsense measure fully in the spirit of the times and long overdue, and that its adoption will forward the interests of physical science and assist materially in the development of the science of optics.

Obituary

Mr. P. M. C. Kermode

MR. PHILIP MOORE CALLOW KERMODE, for many years the foremost authority on the antiquities of the Isle of Man, died on Sept. 5, at the age of seventy-seven years. The son of the Rev. W. Kermode of Ramsey, he was educated at King William's School, and was called to the Manx Bar in 1878. In the following year he founded the Isle of Man Natural History and Antiquarian Society, with the work of which he was closely identified for the remainder of his life.

Every aspect of Manx archæology and tradition held Mr. Kermode's interest, as was shown in the many contributions made by him to *Yn Lioar Manninagh*, the publication of the Antiquarian Society, of which he was editor. His authority was frequently invoked by the late Sir John Rhys, when dealing with Manx tradition and folklore; but his outstanding contribution to Manx archæology lies in his studies of the Celtic and Norse monuments of the island, and their inscriptions in runic and ogham, of which the results were embodied in "Manx Crosses" (1907), a standard authority, in which breadth of treatment and range of knowledge transcend local interest.

Among Mr. Kermode's more recent discoveries was that of an interesting Norse ship-burial, described last year, which revealed a ship of somewhat unusual type. In 1922, Mr. Kermode was appointed curator of the Manx Museum at Douglas, and in 1929 he received the honorary degree of M.A. from the University of Liverpool.

WE regret to announce the following deaths:

Mr. H. C. Chadwick, formerly curator of the Marine Biological Station, Port Erin, and afterwards research zoologist at the Station, and honorary lecturer in marine biology at the University of Liverpool, on Sept. 16, aged seventy-five years.

Dr. F. H. Hatch, O.B.E., technical adviser to the Mines Department, past-president of the Institution of Mining and Metallurgy, and author of several well-known textbooks on metalliferous mining, on Sept. 22, aged sixty-eight years.

News and Views

Nevil Maskelyne, 1732–1811

ON Oct. 6 occurs the bicentenary of the birth of Nevil Maskelyne—the worthy successor of Flamsteed, Halley, and Bradley—who for forty-six years held the office of Astronomer Royal and will always be remembered as the founder of the "Nautical Almanac". A man of mild and genial temper, Maskelyne was admirably fitted for the post he occupied so long, and at Greenwich steadily pursued the aims for which the Observatory was founded. Ever ready to acknowledge the work of others and to further the interests of science, he gained the esteem of all who knew him, and when, after his laborious experiments on the slopes of Schiehallion, Perthshire, made to determine the density of the earth, he was awarded the Copley Medal of the Royal Society, Sir John Pringle in addressing him said that the Council presented him with the medal not only as a token of their acknowledgment of his work but as a "sincere pledge of their affection".

Maskelyne was born in London on Oct. 6, 1732, being the son of Edmund Maskelyne of Purton, Wiltshire. At the age of nine years he was sent to Westminster School, and it is said that, like Lalande and Messier, he was attracted to the study of astronomy by the solar eclipse of 1748. From Westminster School he proceeded to Cambridge, entering first Catherine Hall and then Trinity College, graduating as seventh wrangler in 1754. The following year he took holy orders and was appointed to a curacy at Barnet. He next took the degree of M.A., was made a fellow of Trinity, and in 1758 became a fellow of the Royal Society, his first paper to the Society being written in 1760. Already known to Bradley, in 1761 Maskelyne was sent to St. Helena to observe the transit of Venus in order to determine the parallax of the sun, and two years later sailed as chaplain of the *Princess Louisa* on a voyage to Barbadoes, during which he tested the accuracy of Harrison's chronometer. The death of Bliss in 1765 leaving the office of Astronomer Royal vacant, Maskelyne was appointed to it. He had already in 1763 published the "British Mariner's Guide", and he was now able to prevail upon the Government to issue that eminently useful work the "Nautical Almanac". The almanac for 1767 was published in 1766, and for the succeeding forty-five years subsequent editions were superintended by Maskelyne. In connexion with his constant efforts to improve navigation, he edited the important lunar tables of the German astronomer Tobias Mayer (1723–1762); and obtained for Mayer's widow a grant of £3000, and for Euler, whose lunar theory he used, a grant of £300. Though in early life Maskelyne became a clergyman and afterwards received the degree of D.D., and was given the livings of Shrawardine, Shropshire, and North Runcton, Norfolk, most of his time was spent at Greenwich Observatory, and it was there he died on Feb. 9, 1811.

International Congress of the History of Medicine

The ninth International Congress of the History of Medicine was held at Bucharest on Sept. 10–18, under the presidency of Dr. Victor Gomoiu, with King Carol II., who opened the Congress in state, as president of honour. Two principal subjects were chosen for discussion, namely, the evolution of medicine in the Balkan States, on which papers were read by representatives from Albania, Bulgaria, Czechoslovakia, Greece, Rumania, and Turkey, and the defence of Europe against plague, to which subject the chief contributions were made by Prof. Ricardo Jorge, director of public health at Lisbon; Prof. J. Guiart of Lyons, Prof. P. Capparoni of Rome, Prof. D. Giordano of Venice, Prof. G. Sticker of Würzburg, and Prof. L. Zembruski of Warsaw.

In addition, a number of miscellaneous papers were presented, including the history of medicine and scientific criticism by Prof. A. Castiglioni of Padua, the development of operative gynæcology by Dr. I. Fischer of Vienna, the history of spectacles by Prof. W. Reis of Lemburg, Polydore Vergil by Prof. J. F. Fulton of Yale University, and Chaucer and medieval medicine by Dr. J. D. Rolleston, delegate of the British Government and the Royal Society of Medicine, who, like other national delegates, was elected honorary member of the Royal Rumanian Society of the History of Medicine and awarded the Rumanian Order of Cultural Merit (Class II.).

During the Congress visits were paid to the Faculty of Medicine, Prof. J. Cantacuzène's institute of serums and vaccines, Prof. M. Minovic's medico-legal institute, and various hospitals and museums, as well as to places of general interest. The last three days were spent in a motor tour through the country in the neighbourhood of Bucharest, with visits to sanatoria, the hospital at Sinaia, and the petroleum factory at Campina. A section of the Congress of the History of Sciences to be held next year at Warsaw will be devoted to the history of medicine, so that the next Congress of the International Society of the History of Medicine will not be held until 1935, when the meeting-place will probably be Madrid.

Aeroplane Height Record

On Sept. 16, Mr. C. F. Uwins, chief test pilot of the Bristol Aeroplane Company, Ltd., attained a height of 43,976 ft. (about 8⅓ miles) in a Vickers Vespa biplane, and on Sept. 23 this height was officially confirmed as the absolute height record. The engine used was a Bristol Pegasus nine-cylinder air-cooled radial, which is now in common use in Service machines. The engine develops 900 h.p., and for the purpose of the attempt on the height record was fitted with a larger supercharger than is fitted normally. Mr. Uwins felt very little personal inconvenience at the great height achieved. He wore electrically warmed clothing and also had an oxygen supply apparatus. The previous absolute height record was that set up by Lieut. Apollo Soucek of the United States Navy, who reached a height of 43,181 ft. on June 4, 1930.

Roman Road and Bridge, Rochdale

The repair of the bridge carrying the Roman road over the stream at Black Castle Clough, Blackstone Edge, having been completed (see Nature of Sept. 3, p. 340), the bridge was declared open by Sir Alfred Law on Aug. 20, when members of the Rochdale Literary and Scientific Society and a deputation of Halifax antiquarians were present. Some interesting particulars relating to the Roman road and the bridge were given by Mr. W. H. Crump of Leeds. It would appear that the Roman road, which served the traffic between Yorkshire, Rochdale, and Cheshire, fell into disuse in the year 1740 and had not been repaired since that date. Other old bridges in the neighbourhood are a packhorse bridge which was about ten feet wide, and another, eight feet wide, which carried the road to Oldham. The width of the bridge, now restored to its original seventeen feet, was far greater than anything required to carry the traffic of the district at any time since Roman days. The course of the packhorse road to Lydgate can still be seen on the adjacent hillside. In places it crosses the Roman road, in others it is some distance away. Its relation to the bridge can be seen from the fact that part of the pack-

horse road was destroyed in quarrying the material from which the bridge was built. The bridge now bears the inscription, "Restored 1932, J. H. Price", to commemorate the fact that the restoration was carried out on the initiative and under the supervision of Mr. Price. As previously mentioned, the workmen were volunteers from the unemployed, and material was given or lent by local contractors.

Undeciphered Scripts

According to a letter from Sir Denison Ross in the *Times* of Sept. 21, M. Guillaume Hevesy, a Hungarian resident in Paris, has discovered that a number of the signs of the prehistoric Indian script on seals from Mohenjo-daro also appear in the script of the Easter Island inscribed wooden tablets, while some of the Easter Island signs, not present on the Indian seals, are to be found in the proto-Elamic of Susa. It would now be interesting to hear whether there is any coincidence in the interpretation of the prehistoric Indian signs suggested by Sir Flinders Petrie (see Nature, Sept. 17, p. 429) and those suggested for the Easter Island script in the Report of the Committee of the Royal Anthropological Institute of which Mr. Sidney Ray was chairman. The suggestion of a connexion between the two scripts is not the only attempt to find an affinity between Easter Island and this part of Asia. M. J. Hackin, of the Musée Guimet, has recently directed attention to the resemblance which has been noted between the wooden statues, probably ancestral, which were objects of reverence among the Kafirs of Afghanistan before they were overwhelmed by Islam, of which examples are now preserved in the Kabul Museum, and the well-known statues of Easter Island. The resemblances certainly are strong, although it might be argued that they do not go beyond what may be due to the limitations of an undeveloped technique. It must also be admitted that when the material which it is sought to bring into relation is so widely separated in date as in these instances, the comparison, in default of intervening links, carries more interest than conviction.

The Development and Use of Talking Films

Every improved facility of communication has profoundly affected civilisation. The telegraph and the telephone and the widening of their scope by radio waves have benefited mankind. In the *Journal of the Franklin Institute* for August, H. M. Wilcox points out that the latest outcome of science, the talking film, has many useful applications for social and educational purposes which are not yet fully recognised. For example, a test was recently conducted at the Teachers College, Columbia University, to find the relative values of private study and seeing and hearing a talking film. Certain highly technical aspects of the training of teachers were presented by a talking film which lasted twenty minutes. Half of a group of students attended this, whilst the other half were given the monograph from which the film was constructed to study for half a day, but did not see the picture. A subsequent examination showed that the former group attained considerably higher marks than the latter. The author also lays stress on the fact that the talking film can democratise education in much the same way as it has democratised the dramatic stage. The great teacher can be taken to students in the most remote districts, and material presented to them which hitherto has been available only for the chosen few.

Mr. Wilcox also shows how highly technical are the problems of recording and reproducing sounds. Sound is judged by its pitch, volume, and quality (timbre). The pitch is measured by the frequency, the range being 16-16,000 cycles per second, and is frequently called the sound spectrum. The volume or loudness is measured in terms of energy intensity or pressure. Since the ear hears logarithmically, this is expressed in terms of logarithmic units called decibels. One decibel is approximately the smallest change in volume which the ear can detect. The quality depends on the presence of overtones, the frequency of which is an integral multiple of the fundamental tone. Male speech has a range of 100-250 cycles, and female speech, 200-500 cycles. Practically none of the characteristics of speech by which we recognise one articulate sound from another is particularly influenced by varying the fundamental. Early experience with talking films proved that, unlike silent films, the acoustic properties of the theatre itself had to be taken into account. This showed that both qualitative and quantitative acoustic measurements had to be made. This has led to the development of special instruments, the frequency analyser, the level analyser, the reverberation meter, and the noise meter, which are now successfully used for analysing the acoustic conditions in theatres, and in many other places as well. The success of the recent piano recital by Paderewski before an audience of 16,000 in Madison Square Garden without the use of any sound amplifying device shows what can be done by proper acoustic treatment.

The Swiss Broadcast Network

Practical experience seems to prove that radio transmission can only be utilised to its greatest advantage when wire connexions are used in part of the circuit. In the early days radio was a competitor with wire transmission, but now it co-operates with it, the co-operation being to their mutual advantage. The transmitting stations in a broadcast system are situated outside the cities where the studios are situated, and are connected to them by wires. In *Electrical Communication* for July, A. Muri, chief engineer of the postal administration at Bern, gives an interesting account of the Swiss broadcast network. For broadcasting purposes, Switzerland is divided into three zones. For French-speaking Switzerland, the main transmitter is at Sottens and is fed by the studios at Lausanne and Geneva. For German-speaking Switzerland, the main transmitter is at Beromünster and there are two relay transmitters at Bern and Basel. All three transmitters broadcast the same programme, and are fed from the studios at Zurich, Bern, and Basel as required. The main transmitter for Italian-speaking Switzerland is still under construction at Monte Ceneri. When completed it will be

served by the studio at Lugano. In order to meet the requirements for music transmission, circuits having a cut-off frequency of 10,000 are provided. This enables a sound spectrum of 35-7500 cycles per second to be obtained without distortion. In addition, there exist lightly loaded circuits having a cut-off frequency of 6800 cycles, giving a range of 150-5000 cycles for broadcast speech transmission. At present 87 per cent of all the toll circuits are in underground cable.

Broadcasting and Television in France

La Nature for Sept. 1 is devoted exclusively to an inquiry on television and broadcasting. The views of several eminent technicians both in France and other countries are given. Manfred von Ardenne takes an optimistic view of the progress of television in Germany and looks forward to a great increase in the art before next winter. Maps are given showing a national scheme for radio diffusion in France and comparing it with the present system. A description is given of the new short-wave transmitter in Berlin, the largest in the world. Power of 15 kilowatts is emitted by waves seven metres long. It will help in the solution of certain problems in television and in producing broadcasting free from disturbance. The legal aspects of the problems which arise when a 'listener' is disturbed by induction from apparatus working in the neighbourhood are considered at length. Several law cases are quoted which show that the rights of listeners are recognised in France, and that those who use apparatus which interferes with the working of a private user's set are liable to substantial fines. The disturbances may be due to an electric motor driving a gramophone, neon tube lighting, the working of a cinema, the electric bell system on the ground floor, and public electric supply systems. In certain cases the use of devices to prevent interference is enforced. In conclusion, the influence of American improvements on the design of French receiving sets is discussed.

An Early Diffraction Grating

THE June issue of the *Journal of the Franklin Institute* contains two interesting letters from the second volume of the *Transactions of the American Philosophical Society* (1786), from which it would appear that a transmission grating had been used to produce spectra prior to the work of Fraunhofer (1820). The first, which is addressed to David Rittenhouse from F. Hopkinson, of Philadelphia, has a description of the appearance presented when a street lamp is viewed through a silk handkerchief, and contains a request for an explanation of the pattern formed. The second, dated eleven months later, is Rittenhouse's reply. From its contents, and the lapse of time from the first letter, it appears that he had given considerable thought to the matter. Starting with the observation that the experiment is more curious than one would at first imagine, Rittenhouse then describes the grating he made to perform it with more accuracy. He constructed a square of parallel hairs, about half an inch each way, laid into the threads of two fine screws, with a pitch of 106 to the inch, which he had cut from brass wire. With this he observed a small opening in the window shutter in a dark room, at first with the unaided eye, and later with a prismatic telescope and micrometer, to measure the angular separation in units of the pattern. Six orders of diffraction were observed on either side of the zero, and measured up, and he noted that the dispersion of colours was in the opposite sense to that obtained with a prism, which he considered parallel to Newton's observations on the colours of fringes at the edges of shadows. Rittenhouse was unable to carry out the calculation of wave-lengths from his observations, as Fresnel's theory of diffraction did not appear until 1815, but his data lead to quite good results: 6200 A. for the red, and 4600 A. for the blue. He does not appear to have followed the work up further, so far as this correspondence goes. Fraunhofer's work was of course the more complete, but this experiment is interesting as coming in the gap between the time of Newton and that of the great optical researches of the early nineteenth century.

Hydro-electric Power on the Dnieper

A REPORT from Washington states that "Dneprostroy" was dedicated on Aug. 25. This hydro-electric power project on the Dnieper River, with a capacity of 756,000 h.p., is the largest in the world. The power will be available for metallurgical and chemical industries and to irrigate the rich but droughty steppes. Ships from the Black Sea will now be able to penetrate hundreds of miles farther inland. The cost is approximately 110,000,000 dollars, and the dam, the largest ever constructed, was constructed ahead of the schedule. The dam is 3350 feet long and 140 feet high to the crest of the spillway, above which water may rise 30 feet during floods. The structure impounds a flow varying from 6300 to 835,000 cu. ft. a second at times of large freshets. Six of the nine power units are now being installed. The turbines have a rated capacity of 84,000 h.p., and 100,000 h.p. under a maximum head of water. The maximum or high-water capacity is 900,000 h.p., but owing to irregular flow, only three of the units can be operated during the entire year.

Agriculture in the East of England

THE report on an "Economic Survey of Agriculture in the Eastern Counties of England" issued by the Department of Agriculture, University of Cambridge, and published by Messrs. Heffer and Sons, Cambridge, price 2*s*. 9*d*. post paid, presents an analysis of the financial results for 1931 of nearly a thousand farms in the province. During the year farmers in this area experienced heavy losses. The general price level of agricultural produce averaged 18 per cent below that necessary to provide occupiers with a reasonable return for their own labour and capital investment. The majority of those farmers who were fortunate enough to secure a profit enjoyed special marketing facilities, retailed milk or concentrated on the production of livestock and livestock products, or both. As the eastern counties are generally described as a grain-growing area, it is rather surprising to find that while sales of cereals amounted to less than 14 per cent of the gross income, sales of livestock and their products

represented nearly 70 per cent. The very low prices obtainable for the 1931 cereal crops influence these proportions, but even taking this into consideration, cereals can be described as an important cash product on the larger farms only. The success of the small farmer, and these form the majority, is more dependent on the price of livestock and feeding stuffs than on those of cereals. Interesting comparisons are made of the organisation of the agriculture of the principal farming localities of the province: for example, central Norfolk light loams, the Norfolk 'breck', central Suffolk heavy soils, south Essex London clays, south Cambridgeshire gravels, etc. The most depressed areas are the boulder clays of Essex and Suffolk, and the clays in west Cambridgeshire and Huntingdonshire. The report deals further with main factors influencing profits and with many other subjects of interest to administrators and to farmers.

Electricity and the Farmer

A PAPER read by F. E. Rowland at the Royal Agricultural Show, Southampton, on July 7 and printed by the B.E.D.A. (British Electrical Development Association, Inc.) of 15 Savoy Street, W.C.2, gives helpful hints to farmers as to the best way to apply electricity to their farms. The price of the unit is taken as 2*d*., and when it can be obtained at this price a good case is made out for using electric power. In many cases when space is limited, as in stackyards, electric drive has many advantages. 18 sheep can be sheared per unit expended, or 45 horses groomed, or 12 horses clipped. Motors can be rolled from one part of a farm to another inside wooden drums. Excellent and economical methods are given of lighting farm buildings and roads. Electrically driven pumps provide automatically a plentiful supply of water for all purposes. The use of electric milkers which require a $\frac{1}{2}$-h.p. motor is becoming widespread in England. In New Zealand 15,000 are in use. By the expenditure of one electric unit, 22 cows can be milked, 120 lb. of butter churned, or 1000 bottles washed. Accurate data are given as to the effect of poultry lighting in stimulating egg production.

A New Journal of Animal Ecology

IT is gratifying to find that zoological analysis, having for long been largely confined to the laboratory, is being pushed with vigour into the open country, the obvious place for testing and resolving some of the big problems of animal life. So insistent has been the demand for space to publish the results of observations upon animal populations, their distribution, fluctuations in numbers, migrations and the like, and to concentrate observations of the kind for the convenience of field-workers and zoologists in general, that the British Ecological Society has decided to issue, twice a year, a *Journal of Animal Ecology*, under the editorship of Charles Elton, assisted by A. D. Middleton. The first number, which appeared in May from the Cambridge University Press, is an attractive volume, in appearance as well as in matter. It contains many-sided contributions, from studies of the fluctuations of insect populations in wheat and of bird numbers on an Oxfordshire farm, to a rookery census, an analysis of the ranging habits of wood-ants, and an account of the biology of the fruit-bats of Australia. There are many illustrations, and a useful reference list contains summaries of papers dealing with animal ecology. Members of the British Ecological Society (Secretary, Dr. H. Godwin, Botany School, Cambridge) obtain the *Journal* for their subscription of 25*s*., to non-members the price is 30*s*. The magazine promises to make a niche of its own in British zoological literature, and the interest of its outlook ought to draw many supporters. We understand that so far as suitable material is concerned its success is assured.

Acta Phaenologica

THE new bi-monthly international journal *Acta Phaenologica* aims at concentrating the hitherto scattered studies in phenology and offering an opportunity to "set forth various tendencies, stages of development, points of view of different centres of phenological experiment, and by giving a chance to consult on aims and methods, to achieve useful and active collaboration". The journal is issued under the editorship of the board of the Phenological Association of the Netherlands, and in the first part (Sept. 1931: Publ. Martinus Nijhoff, The Hague) the Secretary, Dr. H. Bos, writes on the scope and prospects of phenology. In the same number there are articles by J. Edmund Clarke on "The Cold Spring of 1929 in the British Isles" and S. Illichevsky on "The Results of the Phenological Observations at Poltava (U.S.S.R.)". The second part includes contributions from Prof. Ihne on "The Beginning of the Phenological Spring in Central Europe during the Ten Years' Period, 1921–1930", Prof. Poggenpohl on "Phenological Observations, 1886–1907", and Dr. H. Bos on "The Dropping of Small Fruits after Blooming". Contributions are accepted in English, French, or German, and each is accompanied by a translation of its title and a short summary of the contents in the two other languages.

Habits of the Woodpecker

ALTHOUGH a tame woodpecker is mentioned by Aristotle, the birds of this family have never been favourites with aviarists, and even the London Zoological Society, after having exhibited at different times no less than seventeen species, had been without a specimen for years until a family of the British greater spotted species arrived recently, and were accommodated with a special cage in the Bird House. Here they attract attention by their extreme activity, which is very characteristic of woodpeckers; they contrast in this respect with their nearest allies the barbets, of which several species are on view, much as tits do with finches. It is of interest to note, however, that the pair-toed feet, often supposed to be an adaptation for climbing, are to be found in the more primitive group of barbets, which do not climb, and that these peck wood when excavating a nest-hole, although their beaks are not specialised into the chisel-type of the woodpeckers' bills, and they do not

dig for food. Thus the woodpecking habit would seem to be older than the woodpecker; and that the pair-toed foot is not specially adapted for climbing is also shown in the fact that in several genera of woodpeckers the hallux or true hind-toe is absent or aborted, so that the foot ceases to be pair-toed.

Detecting Insect Pest Attacks

MR. A. M. MASSEE, of the East Malling Research Station, is to be congratulated on his simple methods for early detection of epidemics of certain insect pests of fruit trees (Ann. Rep. East Malling Research Sta., 1931, pp. 78-80). For example, attacks of caterpillar, aphis, or sucker can be detected if twigs from trees in various parts of the orchard are caused to produce growth early by placing them in water in a warm place. The growing spurs reveal the presence of pests which would not be recognisable in the ordinary way until the natural time of bud break. It is also possible to spray black currant bushes against big bud mite at the most effective moment, namely, just when the mites are migrating. A few affected branches are placed in a jar containing sand and water in the open; daily observation with a hand lens will show when the mites appear on the outsides of the buds, and so will also indicate when spraying should be performed. The idea will help materially to raise horticulture to the status of a more exact science.

Modern Milk Production

SUCCESS in dairy farming depends on the exercise of efficiency with economy in all departments of the industry. The main factors concerned in the cost of production are the milk-producing quality of the race and herd, the care given to breeding for milk production, housing, feeding, and general management. For the guidance of dairy herdsmen, the Ministry of Agriculture has issued a pamphlet (Bulletin No. 52, price 9*d*. net) in which all these factors are considered, and in which the most up-to-date methods of milk production are set forth clearly and in well-classified arrangement. The Ministry has had the advantage of the assistance of experts who have carried out extensive investigations into the many questions connected with the business of milk production, and it goes almost without saying that the result is an attractive as well as a highly practical guide.

A Serious Poultry Disease

THE Ministry of Agriculture and Fisheries issues a warning against the possibility of introducing the disease known as bacillary white diarrhœa into flocks by the purchase of infected chicks from hatcheries. Serious losses may be caused by such agency, the more to be regretted as a little preliminary precaution might have avoided the introduction of the disease altogether. It is conveyed to the chicks by infected hens through their eggs, so that it is of the utmost importance that the breeding stock should be free from the disease. Now, hens which are carriers of the disease may be recognised as such by the agglutination test, and eliminated from the breeding stock; so that a purchaser of eggs for hatching or day-old chicks should insist that the stock from which his supplies are obtained has been declared free of reacting birds. A number of county authorities for agricultural education now accredit poultry-breeding farms where the quality of the breeding stock reaches an approved standard, and where birds have been subjected to the agglutination test according to regulations laid down by the scheme.

Lecture Tours at the Natural History Museum

OWING to the success achieved by the appointment of guide-lecturers at the national museums and galleries, it has been decided to inaugurate more advanced lecture tours at the British Museum (Natural History), to be conducted by members of the scientific staff of the Museum, on Mondays at 12 noon, commencing on Oct. 3. It is announced that Miss M. R. J. Edwards has been appointed official guide-lecturer at the Museum in succession to the late Mr. J. H. Leonard, who died at the end of last year (see NATURE of Jan. 2, p. 15).

Announcements

MR. W. F. HIGGINS, principal assistant of the physics department of the National Physical Laboratory, has been appointed secretary of the Laboratory in succession to Mr. F. J. Selby, who recently retired.

MISS PENELOPE JENKIN, of Newnham College, Cambridge, has been appointed by the trustees as Ray Lankester investigator at the Marine Biological Laboratory, Plymouth, for the year 1933. Miss Jenkin will attempt to correlate the rate of photosynthesis of diatom cultures immersed at different depths in the sea, off Plymouth, with photoelectric measurements of light penetration made by Dr. W. R. G. Atkins.

A DEMONSTRATION of contraceptive technique will be given at the Clinic of the Society for Constructive Birth Control on Oct. 5, at 2.30-5 P.M., to medical practitioners and senior medical students only, who will be given an opportunity of practising various methods under tuition on women patients. Lectures and demonstrations will be conducted by Dr. Beddow Bayly and Dr. Evelyn Fisher and the midwife-in-charge. Applications for tickets (which are necessary) should be made to the Honorary Secretary of the Society, 108 Whitfield Street, W.1.

APPLICATIONS are invited for the following appointments, on or before the dates mentioned:—An engineer in the Burma Marine Service—The High Commissioner for India, General Department, India House, Aldwych, London, W.C.2 (Oct. 15). A Lawrence research student for research in some subject related to the cause and cure of disease in man and animals—The Assistant Secretary of the Royal Society, Burlington House, London, W.1 (Oct. 24). A professor of chemical technology at the University of Bombay—The Secretary, Universities Bureau of the British Empire, 88A Gower Street, London, W.C.1 (Nov. 7). An assistant to teach general mechanical engineering at the Darlington Technical College—Chief Education Officer, Education Office, Darlington.

Letters to the Editor

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, nor to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

Selective Transmission of γ-Radiation by Lead

SEVERAL workers have recorded an apparent anomaly in the γ-ray absorption of lead. Investigations carried out in this laboratory seem to throw new light on the phenomenon.

The mode of attack consisted in the continuous comparison of the γ-ray transmission through pairs of screens, lead and bismuth, lead and thallium, lead and copper, etc., when using as the source of radiation the ageing active deposit obtained in freshly filled radon

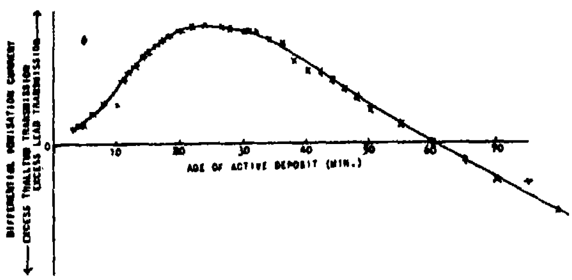

FIG. 1.—Selective γ-ray transmission from radium B through lead as compared with thallium. Source—80 m.c. radon. Screens—0·3 m.m. lead and 0·3 m.m. thallium.

containers. Comparisons carried out before the attainment of the transient equilibrium between radium *B* and *C* show that the transmission ratios Pb/Bi Pb/Tl gradually increase to a maximum and then decrease. An uncorrected set of readings obtained when using a method in which the differential ionisation currents were measured is shown in Fig. 1.

It would appear from these experiments that *a substance is selectively transparent to some at least of the radiations emitted by its radioactive isotope.* A more detailed account of the method of observation and the results obtained will be published in another place.

Magnetic Moment and the Chemical Bond in Alloys

FORRER,[1] Sadron,[2] and Néel[3] have recently published several articles in which they compute the elementary moments of different substances at small concentrations in nickel alloys. Their empirical results are interesting, but their theoretical conclusions cannot be brought into agreement with modern views on atomic structure.

The empirical material may be re-interpreted on the basis of the following assumptions: 1. According to Stoner,[4] pure nickel consists, at low temperatures, of 40 per cent neutral atoms with zero moment and 60 per cent singly ionised atoms with a moment equal to 1 Bohr magneton (M_B). 2. Every foreign atom entering the nickel lattice becomes singly ionised. 3. The number of ionised atoms in the alloy at low temperatures, with small concentrations of foreign metals, is related to the number of neutral atoms in the same way as in pure nickel. 4. Contrary to my previous view, the conduction electrons do not play any important rôle in ferromagnetism.

With these assumptions, the following values for the effective magnetic moments per atom may be calculated from Sadron's data:

$$Ni^{+}1 \quad Cu^{+}0 \quad Zn^{+}-1 \quad Al^{+}-2 \quad Sn^{+}-3 \quad (M_B).$$

The negative values of the moments of Zn^{+}, Al^{+}, and Sn^{+} correspond precisely to the number of valence electrons left attached to the corresponding ion. This remarkable fact may be interpreted as follows: The positive 1 M_B moment in nickel is produced by one 'missing' electron in the incomplete 3*d* shell, as pointed out by Stoner; while the negative moments are produced by 'superfluous' electrons of the corresponding ions. This leads to the conclusion that the secondary valences are compensated by mutual atomic linkage; so that a Zn^{+} ion destroys one elementary magnet (equal to 1 M_B) in Ni^{+}, an Al^{+} ion destroys the magnetism of two Ni^{+} ions, and a Sn^{+} ion of three. This interpretation enables us to understand why a Pd^{+} ion, which possesses a missing electron, a 'hole', in the 4*d* shell, plays the rôle of a ferromagnetic in nickel, with the same moment as nickel itself. A study of the nickel-iron and nickel-cobalt alloys shows that iron inside nickel has $3M_B$, due to 3 missing electrons, and cobalt $2M_B$, due to 2 missing electrons in the 3*d* shell. The same ionic states are found from susceptibility measurements above the Curie point as from magnetic saturation values at low temperatures. This is shown in the following table:

Metal.	Electronic State of Singly Ionised Atom.	Magnetic Moment from Saturation Value (M_B).		Magnetic Moment from Susceptibility (Weiss units).[5]	
		Calc.	Obs.	Calc.	Obs.
Fe	d^7	3	3·2	22–26	20–22
Co	d^8	2	1·8	14·5–17	15
Ni	d^9	1	1	9–11	8–9

These results seem to open up a new approach to the problems of the chemical bond in metals and of the inner structure of ferromagnetic alloys.

Influence of Light on the Gorging of *Culex pipiens* L.

IN connexion with the account given by Dr. Tate and Miss Vincent, in a recent letter to NATURE,[1] of experiments made by them and other investigators regarding the biting habits of *Culex pipiens* in England, the following corroborative observations may possibly be of interest.

During a long series of experiments carried out by us last year, in the course of which female mosquitoes of various species were fed in *daylight* upon human blood, we found that females of *Anopheles maculipennis, claviger, plumbeus*; *Theobaldia annulata, subochrea*; and *Aedes caspius, maculatus, rusticus, detritus, punctor, geniculatus* would bite readily enough. Females of *Culex pipiens*, on the other hand, were

induced to take human blood on seven occasions only, details of these cases being given in the following table:

Number of *C. pipiens* Females induced to bite.	Date (1931).	Time of Day.	Temp. (Cent.).	Percentage Humidity.
1	June 26	4.15 P.M.	18°	—
2	July 22	5.0 P.M.	19°	80
2	,, 23	5.30 P.M.	20°	75
1	Aug. 27	9.30 A.M.	17°	78
1	,, 28	6.0 P.M.	18°	79

In all our experiments, the mosquitoes (whatever their species) were fed in front of a large window facing east. The female *C. pipiens* which bit on Aug. 27 did so in bright sunshine.

It may be noted that, according to Stitt,[2] the yellow fever mosquito, *Aedes argenteus*, may take its first meal of blood in the daytime, but all its subsequent bites are made during the night. This peculiarity is certainly *not* a characteristic of any of the British species with which we have experimented.

Early in May last we collected a number of *C. pipiens* females shortly after the conclusion of hibernation. In those which had obviously fed recently we found, on dissection, the oval, nucleated blood corpuscles pertaining to birds. The adults which appeared to have fed less recently were set aside for oviposition. One of these, after ovipositing, was induced to take two (daylight) meals of human blood, separated by an interval of eleven days; it was found dead, however, two days later. Although fully gorged after the first of these meals, no further oviposition took place and no fat-body accumulated; the insect being found in an emaciated condition when dissected. The ovaries, though not exhausted, had undergone no development.

Of a number of *C. pipiens* females collected during the latter half of last month, eight were found to be gorged with avian blood.

Vectors of Mediterranean Kala Azar

IT has been previously shown[1] that both *Phlebotomus perniciosus* and *P. major* give high infection rates when fed on Chinese hamsters infected with *Leishmania infantum*. In the case of *P. perniciosus* it was also shown that if the epipharnyx is infected flagellates are deposited during the act of feeding. Further work showed that flagellates from *P. perniciosus* when introduced into the skin of susceptible animals (*Cricetulus griseus* and *Citillus citillus*) produce visceral leishmaniasis. It was therefore concluded that *P. perniciosus* is a vector of Mediterranean kala azar.

Transmission by *P. perniciosus* cannot explain the whole of Mediterranean kala azar, for in material collected from Macedonia by officers of the R.A.M.C. during the War we did not find a single specimen of *P. perniciosus*, neither did we find this species in endemic foci in Syria.

On a recent trip through Greece no specimens of *P. perniciosus* were found, but in the neighbourhood of Argos, a heavy centre of infantile kala azar, and in Athens, where both infantile and canine kala azar occur, *P. major* was found to be common. Because of the purely nocturnal activity of *P. major* and its extreme photophobia after feeding, this species has been previously overlooked in Greece.

It was thought advisable to compare *P. major* and *P. perniciosus* as hosts of *L. infantum*. *P. major* is very rare in Malta, but is common in a limited area near Catania in Sicily. A dog naturally infected with kala azar in Malta was taken to Catania, and wild specimens of *P. major* and *P. perniciosus* were allowed to feed on the animal. Out of 31 specimens of *P. major* 25 became infected, while only 33 out of 119 specimens of *P. perniciosus* became infected. The behaviour of the flagellates in the two species was identical. It therefore appears that *P. major* is a better carrier of Mediterranean kala azar than *P. perniciosus* (assuming the identity of canine and infantile kala azar).

The Expanding Universe

IN NATURE of July 2, Prof. Milne has published a very simple and attractive explanation of the phenomenon that has given rise to so much speculation among recent cosmogonists. The sole defect in his clear analysis is that the material particles that form the universe are taken initially to have been enclosed in some finite space, but without mutual action, or even collisions. I should like to bring to the notice of those interested that the last restriction may be easily removed.

Sundman, in his remarkable work on the three-body problem, showed certain general characteristics of the three-body system to persist under Newtonian laws of motion: that if the total energy is greater than that obtained by approach from infinity, under the mutual forces of attraction alone, then at least one of the three bodies will be ejected to infinity. Further, if the energy is less than this critical value and the particles at any time happen to be closer together than a certain determinate distance, the recession to infinity will again take place.

The importance of this lies in that the results can be immediately extended to the n-body problem, as has been demonstrated by Birkhoff, Chazy, Koopman, and others. By studying the Lagrangian R function formed by the products of the masses with the squares of their mutual distances, it can be proved as before that two groups of the particles are to be distinguished: a slower set and a faster receding set; this, provided that the constant of energy is greater than a critical value, or in the contrary case, the R function is sufficiently small at some time, a considerable number of the particles thus being very close together; regardless of the distribution in space or velocity. The further remarkable fact is that this characteristic of exterior motion seems to persist even for more general laws of force than that of the inverse square of the distance, provided that, for attractions, the force vanishes at infinity; certainly for laws of the inverse cube type, and some others.

Lastly, collisions present no difficulty, as the case of elastic rebound can be regularised for double collisions as for triple collisions by the method of Sundman, and collisions of order higher than two will be very rare indeed. This, with the case of Newtonian dynamics, is enough to show the generality of Prof. Milne's remarks. For the relativistic case, the results should be approximated, provided only a finite dissipation of the energy of the system takes place during

the motion, which is also taken to approximate to the Newtonian case as the density tends to zero.

I am, however, unable to say what the movement would be in case the masses at the centre occasion a 'horizon' of the de Sitter type. If electromagnetic components are present among the forces, the paths may remain bounded instead of receding to infinity, as such forces have a 'non-energic' component.

D. D. Kosambi.

Malleswaram, Bangalore,
July 28.

It is very satisfactory to find that the explanation I have given of the phenomena of the expanding universe can be freed from some of the restrictions which were introduced. The essential point in the explanation, as I pointed out, is that we have to do with an unenclosed system; if the system contains some high velocity particles, it will necessarily expand. Mr. Kosambi points out that the expansion and recession to infinity may also occur under more general conditions. But Mr. Kosambi is scarcely correct in saying that in my explanation "the material particles that form the universe are taken initially to have been enclosed in some finite space". I used the finite occupied sphere surrounded by infinite empty space as the most striking illustration of the principle (it was the way the explanation originally occurred to me), but as I explicitly pointed out, any 'initial' density distribution with a concentration towards one region will give rise to the expansion phenomenon; and for the particular relativistic world-structure which I outlined the initial density-distribution extends throughout *infinite* Euclidean space.

The statistical mechanics of an unenclosed system ("a gas-container with the lid off") requires detailed consideration, for it is significantly different from the statistical mechanics of an enclosed system. In particular, the entropy principle no longer holds in its usual form. Maxwell speculated on the consequences of the existence of a velocity sorter, a 'sorting demon'. An unenclosed universe is itself its own sorting demon, and the pessimistic conclusions of Jeans and others as to an inevitable heat-death for the universe must be viewed with doubt.

If point-events are ultimately found to be confined to a finite 3-spread, mathematicians will be entitled to describe the relationships of these point-events by means of a Riemannian metric; but observation has already compelled the introduction of an *expanding* 3-spread if this line of thought is to be retained, with its manifest difficulties, including the re-introduction of an absolute time. In the meantime I prefer to describe these relationships by means of the infinite Euclidean space of any one observer, together with his own particular time. To speak of 'space' itself as curved or finite is of course meaningless, for 'space' is no objective entity; space and time are merely the observer's dissection of that reality which is the change in the observed mutual relationships of observed material particles—what Bergson called "le devenir", or the process of becoming. To describe this reality we may adopt any conceptual space we choose, provided it has the correct number of dimensions.[1] The space of my first paragraph above is the conceptual Euclidean space of any one observer.

The most general scheme of matter and motion for the ground-plan of the universe, that is, the most general description of the above reality, consistent with the observed facts on which the special theory of relativity was based, appears to be given by the distribution-law (for any one observer)

$$F\left(\frac{Z^2}{XY}\right)\frac{dxdydzdudvdw}{c^6Y^2X^2},$$

where X is the invariant

$$t^2-\frac{x^2+y^2+z^2}{c^2},$$

and Y and Z are respectively the covariants

$$1-\frac{u^2+v^2+w^2}{c^2},$$

$$t-\frac{ux+vy+wz}{c^2},$$

x, y, z, t being reckoned from the natural space-time origin of the observer. The distribution I. gave in my synopsis (Nature, July 2, 1932) was the particular case of rectilinear motions, for which

$$F\equiv\frac{\text{constant}}{[(Z^2/XY)-1]^{3/2}}.$$

In general to any function F corresponds a definite acceleration of each material particle and curvature of world lines. The condition that the accelerations near ourselves, for small velocities, coincide with those predicted by the Newtonian law leads to the relation

$$\frac{4}{3}\pi G\rho=\frac{D}{t^2}$$

where G is the gravitational constant, D is a constant less than unity, ρ is the present mean density of the smoothed-out universe near the observer, and t is the observer's reckoning of the time that has elapsed from the space-time origin; t is to be calculated from $V\sim r/t$ where V is the mean observed recession-velocity at observed distance r. This evaluates ρ as not greater than 10^{-27} gram. cm.$^{-3}$.

The possibility of the construction of a universe which appears to *every* observer to be completely centred round himself, wherever he be, and which at the same time thins away at great distances from himself, removes those difficulties which originally led Einstein to adopt a curved finite continuum for the description of the universe.[2] And the fact that we now observe recession-velocities comparable with that of light destroys any justification for the existence of a 'cosmic time', for there is no longer a co-ordinate system in which the observed velocities of celestial objects are all small compared with that of light.[3] In my opinion, these considerations remove many of the traditional philosophical difficulties concerning time and space as a means of description of matter and motion.

Inheritance of Acquired Characters

In 1815, Lamarck propounded the hypothesis that all which has been acquired, laid down or changed in the organisation of individuals in the course of their life is conserved by generation and transmitted to the new individuals which proceed from those which have undergone those changes.

This doctrine is at present somewhat discredited and Prof. T. H. Morgan recently asserted that the stories in the folk-lore of primitive peoples which take for granted that acquired characters are inherited appeal to our sense of humour, and would long ago have been forgotten or disregarded by men of science were it not that in every generation new illustrations are continually brought forward.

In adducing such illustrations, the difficulty is to prove that the characters in question are outside the

scope of natural selection, that they are non-utilitarian and not correlated with any useful characters. This difficulty would appear to be obviated in the illustration which is now given.

It is noteworthy that many eminent men were begotten by fathers of ripe age: the father of Francis Bacon was fifty-two years of age, of John Herschel fifty-four, of Robert Boyle sixty-one, of William Pitt fifty-one, of Samuel Johnson fifty-three, of John Hunter sixty-five and of Charles Parsons fifty-four. This suggests that capability may be in some degree an acquired character, and that the older the father the greater the chance of it being acquired.

An attempt has been made to determine whether

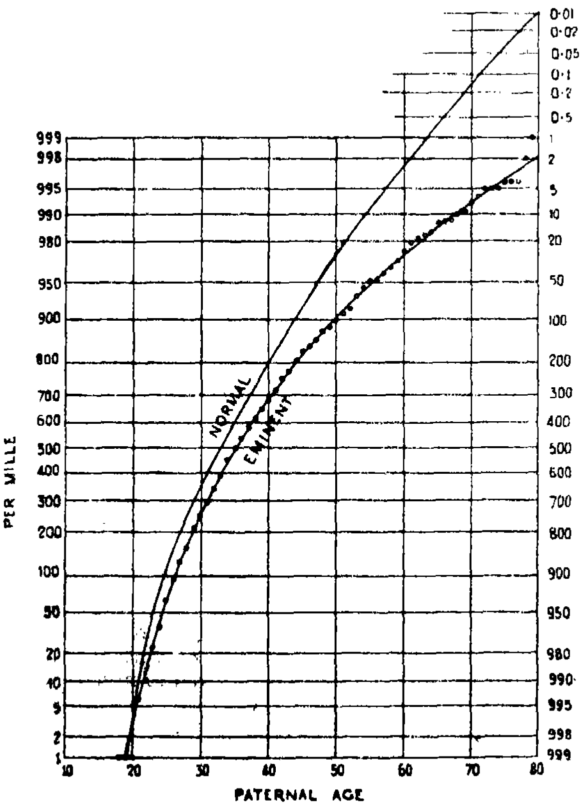

FIG. 1.

this can be substantiated. In the "Encyclopædia Britannica" (Fourteenth Edition) one thousand persons are noticed (exclusive of those mentioned on account of inherited titles) for whom the date of the father's birth is given. These are considered to be of outstanding capability and the paternal age has been compared with that for a more normal population.

The comparison has been made by plotting upon permille paper [1] the frequency distribution of the paternal age both for the eminent thousand and also for one hundred thousand children under one year recorded in the census of Scotland for 1921 (see Fig. 1).

This simple investigation appears to show that capability is an inheritable character acquired by those of mature years. The difference between the two curves in the figure is so striking—the proportion with paternal age more than forty-five years is twice, more than sixty years ten times, and more than seventy years fifty times the normal—that it is thought well to publish the facts without proceeding to examine other statistics.

In compiling the data, it was observed that the grandfathers of many eminent men were of ripe age; Ruskin's father, who was only thirty-five years of age, was born when his father was fifty-three years of age.

Observations on Filmed and Filtered Vowels

REFERRING to Mr. W. E. Benton's letter on vowel sounds,[1] there is a further point to which attention may be directed, namely, the effect of the changes of attitude or 'expression' of the larynx and adjoining parts which accompany vowel formation.

At the International Phonetic Congress at Amsterdam, last July, Dr. Oscar Russell demonstrated the action of his own larynx while articulating various vowel sounds. It was evident that the laryngeal region is very active, and shows a different attitude at each change of vowel.

On the other hand, as Mr. Benton points out, the behaviour of my models showed that recognisable vowel sounds are produced by passing the vibrations of a reed through a pair of suitably tuned resonators in series. It also showed that a complete range of voiced vowel sounds could be produced, over a considerable musical range in each case, by simply altering the effective length of the vibrating reed.

The elaborate adjustments of the laryngeal region are evidently not essential to vowel production; they probably assist by providing in each case a fundamental vibration having overtones in the regions of frequency characteristic of the vowel in question.

Dr. Russell also articulated—in a whisper—some of the so-called voiced and unvoiced consonants (B, P; V, F), and it was apparent that, in this case also, the laryngeal region takes an active part in differentiating the 'voiced' from the 'unvoiced' sound, when both are whispered. This, incidentally, confirms the conclusion which I had drawn [2] from the behaviour of models.

The exact nature of the human adjustments requires investigation.

At my request, Dr. Russell also varied his facial expression while I watched his larynx. It was seen that at each change of facial expression—from a smile to a scowl, for example—there was also a change of expression in the laryngeal region.

This correlation—which also needs detailed investigation—offers a simple explanation of the emotional language of phonation, and completes the gestural picture of human speech.

The mouth gestures of articulation correlate with pantomimic hand or bodily gesture, and the changing attitudes of the laryngeal region correlate with changes of facial expression.

Electron Oscillations

LAST year I made a series of observations on short-wave oscillations in three-electrode valves with positive grid. Details of the experiments will be published elsewhere, but a brief account here, in relation to a theory on the mechanism of these oscillations, as electron oscillations, which I have worked out recently, may prove interesting.[1]

The experimental arrangement was similar to that used by most workers,[2] differing only in a few details.

A system of parallel wires was attached to the grid and plate terminals of the valve. For every position of a movable condenser joining the wires there was a definite pair of values for the grid potential V_g and the emission current i_e which set up oscillations of maximum strength. From V_g and i_e, and from the construction data of the valve, it is possible to calculate the total number N of the electrons between grid and plate.[3] In Fig. 1 the observed wave-lengths λ are plotted against the values $1/\sqrt{N}$ for the following valves: Philips D II, Z I, TA 0810, Radiotechnique R 5, Zenith W 20 A.

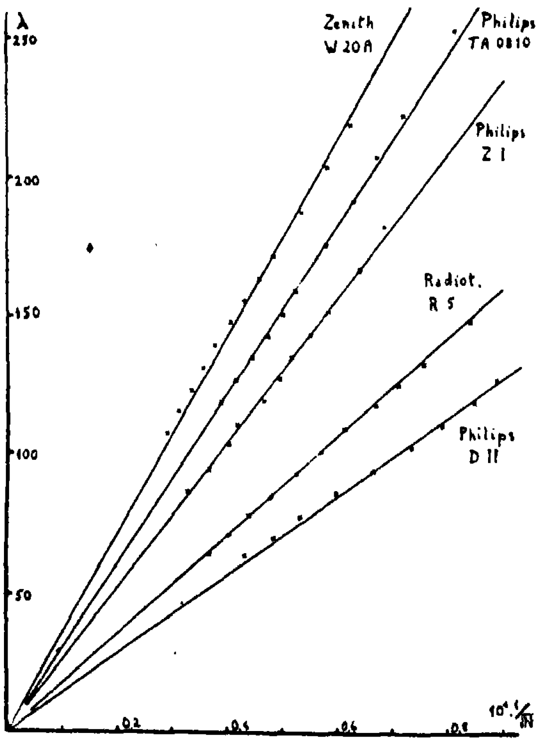

FIG. 1.

The experimental data seem to follow closely enough the theoretical relation $\lambda\sqrt{N} = \text{const} = K$. The values of the constants K for different valves (representing the tangent of the straight lines in the figure) are in reasonably good agreement with the theoretical value (calculated for parallel plane electrodes, omitting space charge effects) $K = 3{\cdot}35 \times 10^6\sqrt{v}$, v being the volume comprised between grid and plate of the valves; this is shown in the following table:

	v.	K.	$K/\sqrt{v}$.
Phil. D II	0·35	$1{\cdot}42 \times 10^6$	$2{\cdot}40 \times 10^6$
Rad. R 5	0·47	$1{\cdot}76 \times 10^6$	$2{\cdot}57 \times 10^6$
Phil. Z I	1·00	$2{\cdot}59 \times 10^6$	$2{\cdot}59 \times 10^6$
Phil. TA 0810	1·16	$3{\cdot}06 \times 10^6$	$2{\cdot}84 \times 10^6$
Zen. W 20 A	1·50	$3{\cdot}60 \times 10^6$	$2{\cdot}94 \times 10^6$

ANTONIO ROSTAGNI.

Science Teaching in Schools

IN several recent issues of NATURE it is suggested that the science teaching in schools is lifeless and dominated by the curse of useless external examinations. I learn that as a result there is little scientific interest or knowledge among the masses, and finally I am cast down by a fearsome picture of the horrors of the machine which science has created.

Turning for consolation to educational periodicals and my colleagues, I find the same story and an atmosphere of desolation such as one associates with a Russian novel.

Unfortunately, this is all true. I cannot say that the position has been exaggerated or put without moderation. Surely the state into which we have drifted has been outlined clearly enough to demand that it is now time to *do* something. Surely science teachers can get together and devise some way out of our trouble, despite the handicap which our specialised university training has given us. Government regulations make it a condition of State aid that a school shall provide facilities for the teaching of science. State-recognised examinations, towards which that teaching is supposed to lead and by which it is valued, permit of a pass on 'Heat, Light, and Sound'.

It is useless to blame the examiner or the teacher. It is the system which accepts such outward and visible signs in place of inward grace which must be fought. Would it not be possible for those of us who have not died mentally under the strain, to band together with the sole aim of improving the outlook? We can leave the economics of the profession to the professional associations. We can sink differences of opinion and teaching rank, and whether elementary school or university teachers, pledge ourselves to claim, in season and out, our right to teach science and not just 'Heat, Light, and Sound'.

The pages of NATURE have been used with moderation and wisdom in outlining this problem. May we look to NATURE to give a lead to such a crusade? It is not the task of many individuals, but of a united body, the members of which are fired with that spirit of untiring pursuit which has marked so much of the history of science.

The Sense of Smell of Cats

I HAD a favourite cat which was having fits and becoming dangerous, so, to destroy it as painlessly as possible, I inserted several grains of morphia in the centre of a piece of foie gras which was cut in two, great care being taken that no morphia was spilt on the outside. The cat on being shown the foie gras expressed in every way its eagerness for it, but when it got within three feet of the foie gras, turned round and looked at me with intense astonishment, and then after another sniff walked away, though previously it had always worried for a small piece. The special point is that the cat could detect something dangerous through the strong smell of the foie gras, though morphia, even in considerable quantities, has to most persons only a faint odour.

Research Items

Anthropometry of the Maya Indians.—In accordance with the policy of the Carnegie Institution (Washington) for making Chichen Itzá, Yucatan, a focal point for correlated research in the archæology, anthropology, linguistics, and biology of Yucatan, Dr. Morris Steggerda, of the Department of Genetics of the Carnegie Institution, has undertaken a study of the physical and physiological characters of the Maya of the villages in the neighbourhood of Chichen Itzá (Publication No. 434, Carnegie Institution). 77 males and 56 females were examined, also 135 children; but the report on the children will appear later. The average age of the male subjects was 30·6 years, of the females 28·8. They claimed to be pure Maya, and although probably no genetically pure Maya exists in Yucatan, they may be regarded as relatively pure, with not more than one-eighth to three-sixteenths Spanish blood. The average eye colour is dark brown, and of the hair, black. The stature is 155·2 cm. for males and 142·8 cm. for females, a range of 10-15 cm. less than United States Indians. Their arms are long in relation to the stature, the lower arm in particular being longer in relation to the whole arm than in the white. They have broad shoulders, being as broad as Plains Indians, who are considerably taller. The Maya is very broad-headed, the cephalic index being 85, the females being 1·2 per cent more than the males. The face is broad, the nasal index still leptorrhine, the ears long and narrow. The relative chest girth in the Maya is astonishingly great, being 56 per cent of stature in males and 58 per cent in females, as against 53 and 55 per cent for whites and 51 per cent for negroes of both sexes. The teeth are very good, 42 per cent of 88 adults having perfect teeth. The pulse rate of the Indian is low and the metabolism high, when compared with whites and negroes.

English Loan-words in Hindi.—According to a study of English loan-words in Hindi by Dhirendra Varma in *Allahabad University Studies*, vol. 8, pt. 1, an "English-educated middle-class gentleman" can scarcely speak a sentence in Hindi without using some English words; and thus a Hindi jargon has grown up which is used invariably by the "English-educated" when speaking among themselves. Among uneducated Indians, English loan-words are in use with a vernacular pronunciation, which conforms to certain phonetic rules or principles. From the point of view of meaning, these words may be classified under certain main heads: (1) words used to convey ideas connected with foreign institutions, such as courts and offices, military and police, educational system, transport and communications, for example, kālij (college), injīniar (engineer), ōbarsiar (overseer); (2) articles introduced by foreign influence—dress, food and drink, machinery, objects of recreation, for example, burus (brush), baeslin (vaseline), timātar (tomato), pancar (puncture). In phonetics, an unfamiliar English sound is replaced by the nearest Hindi sound, while in some cases awkward sounds are dropped or new sounds are introduced to facilitate pronunciation, for example, engine becomes anjan, officer, āphsar; diphthongs are converted into simple vowels, for example, paetmaen, pointsman; a vowel appears to avoid conjunct consonants, phāram, farm, kilark, clerk; or by prothesis, istēsan, station, iskūl, skull, astabal, stable. In consonantal changes, cerebral or dental sounds are substituted for English alveolars, for example, darjan, dozen, Sitambar, September; *c* and *j* are substituted for *t*, *f*, and *dz*, for example, cāk, chalk; *f* and *th* are changed to the nearest stops, that is, *ph* and *th*, for example, phutbāl. By metathesis, general becomes jarnael, and signal singal; *l* is substituted for *n*, for example, lambar for number, and lemonade becomes lamlēt or laemunat, and so forth. The loan-words are mostly nouns. Neuters are assigned to masculine or feminine indifferently; while for purposes of declension English loan-words are treated like Hindi nouns. A full list of loan-words is appended.

Carbohydrates in Relation to Disease.—The abundance of cheap sugar is not only an embarrassment to the sugar industry, but, according to Dr. J. H. P. Paton, also brings risks in connexion with disease (*Edin. Med. J.*, **39**, No. 9, p. 556). Dr. Paton estimates that the average consumption of sugar is now in the neighbourhood of 100 lb. a head per annum. Sugar, as we use it, is not a natural food, and is devoid of all accessory food substances. Excessive consumption of sugar tends to upset digestion, is a factor in the production of rickets and dental decay, and leads to retention of water in the body, with an increased tendency to catarrhal affections. It is probably responsible for the increasing frequency of acidosis in the modern child, and it throws additional work on the pancreas, which may result in degeneration of this organ and diabetes. Experimentally, an abundant supply of glucose promotes the development of cancer in mice, and carbohydrate excess may therefore be one of the factors causing the increased prevalence of cancer.

African Birds and Temperature.—Dr. F. M. Chapman has shown that the distribution of bird-life in South America can be associated with climatic zones related to temperature, and applying a similar analysis to the birds of Africa, W. Wedgwood Bowen has found a zoning comparable to that in South America (*Proc. Acad. Nat. Sci. Philadelphia*, **84**, 259; 1932). Knowledge of the distribution of many species is too inadequate to permit a thorough analysis of the zonal relationships; but, ignoring the alpine and temperate zones, a rough analysis shows that 599 species are limited to the tropical zone and 550 to the subtropical zone, while only 100 occur indifferently in both zones, although 254 more which are common to both zones show subspecific differences which appear to be related to temperature. That is to say, of 1500 species only 100 appear to exhibit no change attributable to temperature. Although the distribution of the vegetation belts in Africa is mainly determined by rainfall, yet the study of Shantz's vegetation map shows that, with one notable exception, each of the various vegetation types may be classified roughly according to life zones (apparently not a chance distribution), and even the exception, the "acacia—tall grass savanna", which ranges widely through tropical and subtropical zones, may, the author thinks, be divisible, from the point of view of bird distribution, into tropical and subtropical portions.

Butterflies of the District of Columbia.—Bulletin 157 (1931) of the United States National Museum is devoted to an extensive memoir (366 pp.) entitled "The Butterflies of the District of Columbia and Vicinity". Its author, Mr. Austin H. Clark, who is curator in the Museum, has in this work provided an admirable non-technical guide to the rich butterfly fauna of the area under consideration. Each species is discussed at variable length, according to any special features of interest associated with it. Also, each species has one or more illustrations devoted to

it, and these figures are comprised in some sixty-four half-tone plates bound at the end of the letterpress. In the long introductory chapter the author contributes a number of interesting remarks and observations on butterfly behaviour. Of especial note is the section dealing with pressure of population, since, in many of the species, he finds that if the males increase beyond a certain proportion they seem incapable of living amicably together in the presence of the females. A familiar sight is a shrinking puddle tenanted by gay companies of newly emerged male butterflies. These, according to the author, are examples that have been driven from over-populated areas by being incessantly tormented by other males. Requiring water, these fugitives naturally resort to the moisture found in puddles, where, in the absence of the females, they exist peaceably. Many of the common roadside butterflies are also stated to be exiles and consist of newly emerged males. They appear to be unable to cope with the older males in their natural habitats and are driven to areas beyond where the females live. As they mature, and the older males die off, they are able to fly back to the fields and, in their turn, drive out any younger and less lusty rivals. Sections devoted to butterflies and storms, the extermination of one species by another, migration, and other features of the biology of these insects are also included in this paper.

Storage of Fruit by Freezing.—Dr. J. Barker and Mr. T. Morris have just published a very interesting leaflet on the comparative values of different methods of storing fruit by freezing (Dept. Sci. and Ind. Res. *Food Investigation Leaflet* No. 2, 9 pp., 1932). The principles and practice of preservation by cold storage are discussed. Freezing alone often results in an inferior product due to the activities of enzymes when thawing takes place. Refrigeration with sugar or syrup prevents the browning of such fruits as plums and cherries during storage, and the destruction of the enzymes of peas or beans by heating slightly before cold storage gives successful results. Quick freezing and freezing in a vacuum or under an inert gas have also been investigated. The special considerations relating to the cold storage of English plums are set forth by Dr. Franklyn Kidd and Dr. C. West in *Leaflet* No. 1 of the same series (6 pp., 1932). The effects of storage temperature, handling, fungal rotting, packing, type of store, and climatic conditions before harvesting are all discussed. The report, though short, gives the results of ten years' intensive work upon the problem.

Bacteriophage of *Pseudomonas radicicola*.—An interesting paper entitled "Studies on Bacteriophages of the Root Nodule Organisms", by Dr. S. V. Desai, dealing with the effect of certain bacteriophages on the activity of the root nodule organisms of leguminous plants, has recently appeared (*Indian J. Agr. Sci.*, vol. 2, pt. 2., 1932). Several strains of bacteriophage were isolated, and it was found that media which were suitable for initial separation were not good for the increase of virulence of the bacteriophage. The different strains were not specific for the various strains of the bacterial host, and it is suggested that there is only one bacteriophage for *Pseudomonas radicicola*, no matter what its host plant may be. The lytic principle was inactivated by heating to 75° C. for five minutes. The results suggest further experiments to determine what part the bacteriophage plays under field or garden conditions. It has been found difficult to separate the organism and its bacteriophage, and it seems possible that the presence or absence of the latter may bear an intimate relation with the observed behaviour of the former.

Correlation of Coal Seams by Plant Spores.—The correlation of coal seams has usually depended on consideration of the associated shales and, in particular, the fossil-bearing bands. One of the most characteristic features of coals are those plant remains which have escaped destruction in the process of coal formation. Of late years, the means for identifying and even isolating the spore exines which are resistant to decay have been perfected and thus provide a method of correlation which may offer advantages over the study of fossils in adjacent strata. This method has been applied to the Parkgate seam in the Yorkshire area, and the Fuel Research Division of the Department of Scientific and Industrial Research has now, in Paper 23 of the Physical and Chemical Survey of National Coal Resources entitled "The Significance of Spores in the Correlation of Coal Seams" (H.M. Stationery Office, 2*s*. net), reported the extension of the study to the Barnsley and Silkstone seams in the same area. In all, 30 types of spore have been distinguished, and although most of them are too few in number or too irregular in distribution to use in identification, there is evidence that certain types are characteristic of certain seams, and the force of these conclusions may grow with increase in the number of observations.

Swedish Rainfall.—The report of the Swedish rainfall stations for 1931 has been published by the Statens Meteorologisk Hydrografiska Anstalt in the Årsbok, No. 13, pt. 2. The data come from 698 stations spread throughout the State. Their distribution is shown on a large-scale map. For every month in the year there is a detailed record of every station and a map of the rainfall. The year proved to be exceptionally wet, with a rainfall that averaged 142 per cent of the normal over the whole country. Only two provinces had a year's total below the average, and many had more than twice the normal rainfall. On the whole, the northern parts were the driest and the areas of the central depression the wettest.

Existence of a Heavy Lead Isotope.—K. Murakawa has published recently a note on the hyperfine structure in the spectrum of lead (*Scientific Paper* No. 371, Tokyo) which illustrates both the value and difficulty of such work. In it he confirms the existence of the light lead isotope Pb^{204} found by Schuler and Jones in a similar manner, but also claims, in opposition to Kopfermann, that there is a satellite to λ4057 which must be attributed to a heavy isotope Pb^{210}. He finds similar satellites to λ3683 and λ4387. A Lummer-Gehrcke interferometer pattern for 4387 is reproduced showing the supposed Pb^{210} component, although without the corresponding microphotometer record. The abundance ratio for Pb^{204} and Pb^{207} is given as 1 : 25, and the ratio for Pb^{204} and Pb^{210} as 8 : 1.

Thermionic Emission.—The subject of thermionics has developed in a few years from the method of studying the electrical properties of matter to being the basis of one of the world's widest commercial applications of physical science. Richardson was the first to state, thirty years ago, that electrons, normally retained in a substance by a potential discontinuity at its surface, are able, when the body is heated, to escape through the surface and so constitute an electric current. The literature of the subject is now widespread and much of it is very abstruse. It was decided by the Radio Research Board that a critical survey of the literature would be of real value to engineers and other scientific workers. The work was entrusted to Dr. W. S. Stiles, of the National Physical Laboratory, and is now published (Radio Research Report No. 11. London: H.M.S.O., 2*s*. 6*d*.). The author

gives a clear and comprehensive survey of all the main results obtained in researches in the various branches of the subject, together with a lengthy and carefully compiled bibliography, which includes references to all the important papers published up to December 1930. This book will prove of great value to everyone interested in thermionics. The author sometimes gives useful hints showing how formulæ given by different authors can be reconciled. His abstracts also will enable the investigator to see what original papers he should consult.

Highly Cracked Gasoline.—In the April number of *Industrial and Engineering Chemistry*, Messrs. C. R. Payne and Alexander Lowy give an interesting account of their work on the study of composition of cracked petrol before and after heat-treatment. Their method, briefly, was to subject this petrol to a temperature of about 300° C., which is actually below the temperature employed in the cracking process, and they reached some interesting conclusions. It was found that the percentage of unsaturated hydrocarbons was decreased by the heat and pressure treatment in all the fractions isolated. The percentage of naphthenes in the whole distillate up to 201·5° C. was increased by the treatment. Additional changes are considered to be attributable to polymerisation, such as increase of material boiling above 201·5° C. by about 4 per cent; disappearance of probable presence of cyclo-alkenes; and formation of hydrocarbons containing hydrogen atoms easily replaceable by halogen. Regarding the composition of the cracked petrol, benzene and toluene were identified in selected fractions; in one fraction, boiling from 20·4° to 35° C., the presence of methylcyclobutane was inferred. A further interesting point is that, in general, the proportion of unsaturated hydrocarbons tends to decrease as the boiling point increases; while in a similar way, the proportion of paraffinic hydrocarbons decreases, and the percentage of naphthenes and aromatics increases, as the boiling point is raised. Although the paper is a comparatively short one, it contains some valuable data on the physical and chemical properties of the various fractions, not easily accessible elsewhere; in particular, the refractive indices on ordinary and treated fractions provide some interesting contrasts.

Astronomical Topics

The Total Solar Eclipse of Aug. 31.—Further bulletins from Science Service, Washington, indicate that several observing parties obtained a fair measure of success. The U.S. Naval Observatory party at Limerick, Maine, was able to carry out its full programme, though thin cirrus cloud was passing. The General Electric Company sent up an aeroplane at Concord, N.H., which reached perfectly clear sky: the moon's shadow was seen for three minutes before and after totality. The Harvard party at Portland, Maine, had a completely clear sky. The Greenwich party at Parent obtained a satisfactory photograph of the flash spectrum extending from H_a to the H and K calcium lines; but the attempt to obtain the infrared portion failed.

At least three different parties of observers, seeing that conditions at their stations were almost hopeless, made dashes by motor cars to regions where the clouds were less dense, and were successful in obtaining views of the eclipse, though of course there was not time to transport large instruments. Excellent roads contributed to the success of this novel resource.

Astronomical Notes for October.—Venus is well placed for observation as a morning star in Leo; it has passed its greatest brilliance, but is still of magnitude −3·7. The illuminated fraction of the disc increases from 0·62 to 0·73, the diameter diminishes from 19″ to 15″. There is a conjunction of Venus and Jupiter (distance apart 7′) on the morning of Oct. 20; they will be high enough for convenient observation soon after 4 A.M.; it will give an opportunity to compare their surface brightness, and hence their albedoes.

Mars is a morning star, moving from Cancer to Leo; its diameter increases from 5″ to 6″; it will be nearly 14″ at the nearest approach to the earth on March 3. Mars will remain fairly near Jupiter throughout this apparition; their least distance apart will be 16′ on June 4. Mars will make a near approach to the moon's south limb at 6.40 A.M. on Oct. 24 next. There will be an occultation in Scotland.

Saturn is still observable in the early part of the night; it is stationary in the eastern part of Sagittarius. The ring has begun to close; its major axis is 38″, its minor 14″; it will be edgewise about the end of 1936.

Uranus is well placed for observation, being in opposition on Oct. 14; it is in the eastern part of Pisces; its diameter is 3·6″; a map of the faint stars near it is given in the B.A.A. Handbook for 1932. Its magnitude is 5·9, so that it is visible to a good eye.

There are two occultations of fifth magnitude stars visible in London; one disappears on Oct. 11 at 6^h 58½^m P.M., 40° from the north point; the other reappears on Oct. 20 at 2^h 36½^m A.M., 230° from the north point.

Comet Peltier-Whipple was visible to the naked eye at the end of August; it is now fainter, but still observable with moderate telescopes; the following ephemeris (for 0 hours on the days named) is a continuation of one by Messrs. Anderson and Cherrington (Harvard Card 239).

	R.A.	N. Decl.
Sept. 30	13^h 47^m 21^s	56° 40′
Oct. 4	13 52 52	54 37
8	13 57 36	52 49
12	14 1 39	51 15
16	14 5 18	49 52
20	14 8 36	48 40
24	14 11 40	47 36
28	14 14 31	46 41
Nov. 1	14 17 12	45 55
5	14 19 41	45 17

Ephemerides for several periodic comets now under observation are given in the B.A.A. Handbook for 1932. It is to be hoped that all who have the means will join in the search for Tempel's comet of the November meteors; if the estimated date of perihelion is near the truth, it would be in Cancer or Leo during October. Search should also be made for Brooks's comet; it is in Pisces, and should be nearly midway between the two ephemerides given in the Handbook.

The most conveniently observable minima of Algol occur on Oct. 11 about 10^h 36^m P.M., and on Oct. 14 about 7^h 24^m P.M.

Summer Time ends at 2^h A.M. on Oct. 2; after that date the times given here are those shown by ordinary clocks. It is well to note that astronomical records should never be made in Summer Time, but always in true Greenwich time.

Forestry in Mauritius

CONSIDERABLY more than twenty-five per cent of the island of Mauritius is occupied by forests and rocky mountains which lie outside the cultivated area. As is pointed out in the Annual Report of the Forest Department of Mauritius for 1930, the great density of population, the small area of the forests (Government forests, Crown and other forest lands, total 92,050 arpents or about 95,732 acres) and the demands made upon them, the many uses to which wood is put, and the local dependence on imported timber, all point to the vital importance of forestry in the island. Since the forests lie mainly on the top and slopes of the central plateau, from which all the important rivers run, it is obvious that their preservation is equally vital to the maintenance of the premier industry of sugar cultivation, in order to prevent erosion and its destructive aftermath, and to secure the maintenance of water supplies, and so forth.

During the year effect was given to a scheme of reorganisation of the Department, in order to introduce better methods of control and to permit of future development. It is unfortunate that this scheme, which reflects the highest credit upon its authors, should have so nearly coincided with present financial stringency. Nevertheless, when the chief commercial interest of the Colony is so intimately bound up with its forests, it may be confidently expected that the recognition accorded to the importance of the Forest Department may not be withdrawn owing to what, it may be hoped, is a temporary financial embarrassment.

The climate of the central plateau of the island is cool, windy, and wet. The two southern masses of forest are by far the largest, and from them the Grand Bassin Division (30,000 arpents) and the Midlands Division (21,000 arpents) have been formed (1 arpent equals 1·044 English acres). The northern block of forest comprises the Nouvelle Découverte Division, of about 5700 arpents. The Divisions are mainly State forest, with some privately owned mountain reserves along the boundaries. Grand Bassin Division contains 2800 arpents of mountain reserves, Midlands Division 500 arpents, and Nouvelle Découverte Division 1000 arpents.

About one-half of the staff is engaged outside the forests in protecting the mountain, river, and road reserves, administering the laws governing those reserves, working the small isolated State forests, and inspecting leased Crown lands, notably a strip of land round the coast, known as Pas Géométriques.

Forest management is under the control of a Forest Board, which held seven meetings during the year, the subjects under consideration consisting of the working of the land purchase scheme, the management of the mountain reserves, and the forms of lease for the Pas Géométriques.

A considerable amount of forest survey work was undertaken, 500 miles of boundary lines cleaned of weeds, and stock maps of the growing stock on 3470 arpents of forest prepared. Roads and a tramway line were also under construction to facilitate the extraction of timber and fuel.

Experiments in afforestation work and the rearing of exotics have been in hand for some years, and recently this work has made great strides. Wide spacing was formerly made use of in plantations, but the policy is now to plant closer, and a considerable amount of work in filling up the old wide-spaced plantations has had to be undertaken in order to obtain satisfactory crops. Tending the new plantations is also given careful attention, and plantation control books have been introduced, the officer concerned filling up data of growth and so forth twice in the year—a most excellent provision. On the subject of this work, the conservator, Mr. G. N. Sale, writes: "During the past fifty years numerous species [of exotics] have been tried, and many found to be suitable for plantations. This work was continued in 1930, and success was obtained in the nurseries with *Pinus caribœa*, which germinated and grew even better than *Pinus tæda*. It is to be hoped that this valuable tree will prove as vigorous in the forest as in the seed-bed. *Pinus palustris* formed luxuriant foliage, but no leader. *Pinus sylvestris*, *Sequoia sempervirens*, and *Ormosia semicastrata* failed in the Nursery."

Animals, especially deer, and weeds appear to be the chief dangers which the forests have at present to fear. It is said that "the number of deer is kept as high as possible by the Lessees of the Shooting Rights over nearly the whole of the State forests". It is not stated what rent is obtained from the lessees; in the latter part of last century, when the King of Saxony desired to have an excessive number of deer maintained in the State forests, he paid a considerable rent for the feeding of the animals during the winter months, and for excessive damage done, in addition.

Under the heading of utilisation, some interesting information is given on the subject of timber and fuel. Most of the timber obtained during the year came from Belle Rive, in Midlands Division. "The timber was extracted partly in the form of logs, which were sent to the Match Factory. Pine scantlings were sold to the Harbour Engineer, who worked the timber, soaked it in fuel oil and used it in the Granary. This form of impregnation was adopted by the Forest Department, and the results will be watched with interest. If the Chinese Pine timber can easily be rendered immune from the attacks of White Ants, the plantations made from 1885 onwards should supply material of the greatest value to the Colony during the next twenty years. The Pine timber proved fairly satisfactory in seasoning, and did not split and twist to any great extent, but the timber of *Eucalyptus robusta* was very difficult to season." The forest felled was apparently patchy; eucalyptus had outgrown the pine, developing large spreading branches. The timber not being straight-grown, it warped and split badly, especially when sawn into boards and planks. Straight-grown eucalyptus, especially *E. tereticornis* and 'E. hybrid', would, it is believed, yield very good boards when carefully seasoned. It is stated that the demand for indigenous timber is steady, if not large; 'plantation timber' of exotic species is much less popular. "It will not be possible to produce any considerable supply of indigenous timber, and it is hoped that when the public becomes accustomed to well seasoned exotic timber, this prejudice will disappear."

Whilst it is obviously to the interest of the Colony to endeavour to raise in plantations such a proportion of exotic timber material as will reduce the imports, yet the neglect to maintain and obtain the regeneration of at least a portion of the indigenous forests would not, we believe, be in the true interests of the Colony or its future. An entire reliance on introduced species is dangerous, and is probably uneconomic in the long run.

A suggestion might be proffered on the subject of the tabular statements in the appendix series. These are not in some cases easy to follow, and in Appendix 9 no totals are given. A statement of the imports of timber and other forest produce into the Colony would be useful. With this minor criticism, it may be said that the Report under review has many points of unexpected interest, and reflects credit upon the Governor, the Forest Board, and the Conservator.

Lighting and Light Sources

AMONG the papers presented in Section 6 of the International Electrical Congress, recently held in Paris, was one by Dr. Pirani, of the Osram Gesellschaft, who gave a very interesting account of recent developments in the production of light. After a general description of the underlying principles of the modern discharge tube, he dealt in more detail with the two types showing the greatest efficiency, namely, the sodium tube and the mercury tube. In the case of the former it has been found experimentally that the addition of one of the rare gases at a pressure about a thousand times as great as that of the sodium vapour is of considerable advantage. Since the atoms of the rare gas require a very high voltage to excite them, they act principally as elastic obstacles in the path of the electrons and so increase a hundred-fold the distance which an electron travels on its journey from the cathode to the anode. The chance of a collision between the electron and an atom of sodium is thus correspondingly increased. When the tube is operating under the most favourable conditions, 70-80 per cent of the energy of the electrons is transformed into light. An over-all efficiency of about sixty lumens a watt can be obtained from a sodium tube.

In the case of the mercury tube, the intensities of the lines in the longer wave-length part of the spectrum are much increased, relatively to the others, by increasing the pressure in the tube to one atmosphere or more. This is illustrated by diagrams showing the relative intensities of the different lines for two tubes operating at pressures of 0·5 mm. and 3 atmospheres respectively. The result is naturally a very great increase in luminous efficiency and lamps can be operated to give 50 lumens a watt. The possibilities of light production by the excitation of gases in the molecular state, and of liquids or solids, are discussed by the author in a final section of his paper, but he concludes that the most hopeful line of work lies with gases in the atomic state or with vapours.

A new type of mercury arc in quartz, stated to have an efficiency of some 10 candles a watt, was described in a paper by Prof. Cz. Reczynski of Poland. It depends on the reduction of the cathode potential drop from 100 volts to about 5 volts by (*a*) using for the cathode a ball of tungsten instead of mercury, and (*b*) placing a tungsten filament at a short distance away from the cathode.

In an interesting communication from Japan, Dr. R. Kurosawa described a method of studying the characteristics of a diffusing material, as regards transmission and reflection. The brightness (not the candle-power) of a sample of the material is measured at all angles of view, the light being incident normally. The measurements are most conveniently carried out by means of a photoelectric cell (that employed by the author is a vacuum type cæsium cell), an image of a given area of the surface of the material being formed on the sensitive surface of the cell. The author recommends Halbertsma's definition of diffusing power (σ), that is,

$$\sigma = \sum^{n} \beta(\theta)/n\beta(o)$$

where $\beta(\theta)$ is the brightness at an angle θ to the normal and n is the number of directions in which measurements are made. The author considers that three measurements, at the angles $22\frac{1}{2}°$, 45°, and $67\frac{1}{2}°$, are generally sufficient. Since $\beta(o)$ cannot be obtained by direct measurement in the case of reflection, it must be deduced by extrapolation from observations made at the above three angles, using Lagrange's formula $\beta(o) = \sum^{3} R_i \beta\left(\frac{i\pi}{8}\right)$ where $R_1 = 1·5412$, $R_2 = -0·6682$, $R_3 = 0·1270$. A nomogram is given in the paper for finding σ from the observed values of β_2/β_1 and β_3/β_1, using the formula deduced by the above method, namely,

$$\sigma = (\beta_1 + \beta_2 + \beta_3)/(4·62\beta_1 - 2·00\beta_2 + 0·38\beta_3).$$

The subject of glare in lighting installations was considered in two papers presented in this section. M. J. Dourgnon, defining glare as the threshold sensitivity of the retina at a given point A (for example, the fovea) with the eye exposed to any given field, proposed that the glare produced by a uniform field having a brightness equal to 1 candle per square cm. should be adopted as the 'unit of glare'.

Ing. J. Ondracek, of Austria, dealt principally with the time required for the eye to adapt itself when the gaze was transferred from a surface of high brightness to one of low brightness, or vice versa. This time is a function of the *average* brightness of the two fields of view and may be expressed in terms of the ratio of these two brightnesses. In the practical case, one brightness is that of the surface being worked upon, while the other is the average brightness of the surroundings, for example, ceiling, walls, and floor.

The use of photoelectric cells for colorimetry was described in a paper by Dr. N. R. Campbell, who outlined the method of colour-matching electric lamps by the use of two cells having markedly different sensitivity curves, and the use of the Toussaint photoelectric colorimeter for giving a rough indication of the spectral distribution of the light reflected from a coloured surface.

Evaporation, Condensation, and Adsorption

DR. I. LANGMUIR (*J. Amer. Chem. Soc.*, July) has extended his well-known adsorption formula by taking account of the forces between adjacent adsorbed particles ('adatoms'). In the simple theory, the rate of evaporation of adatoms from a surface is $\nu_1\theta$, where θ is the fraction of the surface covered and ν_1 a constant. If atoms condense only on uncovered parts, the rate of condensation is $\alpha_0\mu(1-\theta)$, where α_0 is constant, measuring the efficiency of condensation on a bare surface, and μ the rate of collision of incident atoms per unit area of surface, given by the kinetic theory:

$$\mu = (2\pi mkT)^{-\frac{1}{2}}p = 2·653 \times 10^{19} p(MT)^{-\frac{1}{2}} \quad . \quad (1)$$

where p = pressure in baryes, k = Boltzmann's constant, m is the mass of an atom, and M the atomic weight of the gas. For steady states the rates of evaporation and condensation are equal, hence

$$\theta = \alpha_0\mu/(\nu_1 + \alpha_0\mu) = \alpha_0\tau\mu/(\sigma_1 + \alpha_0\tau\mu) \quad . \quad (2)$$

where $\tau = \sigma_1/\nu_1$ = average life of an adatom, σ_1 being the number of adatoms per unit area of saturated surface ($\theta = 1$). Equation (2) represents the observed adsorption on plane surfaces with reasonable accuracy in a surprisingly large number of cases.

The vapour pressure of a liquid is given over a wide range of temperature by

$$p = AT^{\gamma}e^{-b/T} \simeq A_0 e^{-b_0/T}. \quad . \quad . \quad (3)$$

Trouton's rule requires that $\gamma = 0$ and A is a universal

constant; Hildebrand's rule that $\gamma = 1$ and A a universal constant. A comparison with experimental data for liquids shows that Hildebrand's rule gives better results than Trouton's, but a rule which gives still better agreement is obtained by putting $\gamma = 1{\cdot}5$, when $\log A_{1\cdot5} = 6{\cdot}37$. The vapour pressures of solids, the vapours of which have rigid molecules, are also given by this equation with $\gamma = 1{\cdot}5$ and $\log A = 6{\cdot}9$, but much larger values of A are obtained if the molecules possess internal degrees of freedom. It is therefore assumed that such molecules in the vapour phase may possess high internal mobility, as though liquid, whilst at lower temperatures they may become rigid, as though solid. Such effects probably do not exist with molecules of vapours of liquids. This part of the paper contains a detailed and valuable analysis of experimental data.

The ratio of the latent heat of fusion to the melting point has high values for large molecules such as stearic acid, increasing roughly in proportion to the number of atoms in the molecule, and in such cases a large part of the heat of fusion represents an internal heat of fusion of the molecules themselves, which in the solid are rigidly arranged within the lattice, so that the molecule itself is solid, but when the solid melts the molecule also melts.

In considering the evaporation of adsorbed atoms from an adsorbed film containing σ atoms per unit area, the value of τ, the average life of the adatom, being the same for all, the rate of evaporation (atoms cm.$^{-2}$ sec.$^{-1}$) is

$$\nu = \sigma/\tau = \sigma_1\theta/\tau.$$

From (3) in the form

$$p = A_{1\cdot5}T^{\frac{3}{2}}e^{-b/T}$$

where $$b = b_0 - \frac{3}{2}T = \frac{\lambda}{k} - \frac{3}{2}T,$$

λ being the latent heat of evaporation per atom, and (1) in which $\mu = \nu_1 = \sigma_1/\tau$, we find

$$\tau = (2\pi mk)^{\frac{1}{2}}(A_{1\cdot5}T)^{-1}\sigma_1 e^{-b/T},$$

in which it is shown that $A_{1\cdot5} \simeq 8 \times 10^6$, and hence

$$\nu = A_{1\cdot5}(2\pi mk)^{-\frac{1}{2}}\theta T e^{-b/T}, \qquad (4)$$

an equation for the rate of evaporation of atoms or molecules from monatomic films on surfaces which is shown to agree reasonably well with experiment for thorium, oxygen, and cæsium films on tungsten. In (4) the forces of interaction between adatoms are taken into account by the value of b, and since b is in general a function of θ, the value of ν is not proportional to θ except at such low values of θ that b is near the limiting value for $\theta = 0$.

Although the conditions in which adsorbed films more than one molecule thick can be formed are rather unusual, they are discussed. In general, adsorbed molecules on plane homogeneous solids are acted upon by strong forces originating from the underlying solid. The adsorbed molecules thus become polarised and repel one another as dipoles with forces proportional to M^2r^{-4} (M = dipole moment; r = distance), and attractive forces predominate only when two kinds of adsorbed molecules are present which become polarised in opposite senses, as cæsium and oxygen on tungsten or salts on metals, such as mercurous sulphate on mercury. In some cases, however, the forces exerted between solid and adatom are small, as when hydrogen molecules or helium atoms strike a chemically saturated surface such as tungsten covered with adsorbed oxygen. In such cases the average life of the adatom is so small that it does not even reach thermal equilibrium with the solid, so that the accommodation coefficient is much less than unity (0·1 - 0·2).

The equation of state of the two-dimensional gas composing the adsorbed film may be found by the virial method with a repulsive force specified in terms of dipoles:

$$FA = RT + \tfrac{1}{2}\Sigma(rf).$$

A two-dimensional van der Waals equation, in which the long-range forces are now repulsive, takes the form

$$(F - a/A^2)(A - A_1) = RT,$$

in which A is the area containing 1 gm. atom and A_1 in the ordinary derivation considering only first order effects is found to be only half the area actually covered by 1 gm. atom of adatoms. Experimental data for oil films at high surface concentrations show that A_1 corresponds with a close packed film in which the molecules cover the surface completely, and a new theoretical derivation for the case of a high concentration of adatoms confirms this.

The choice of a dipole repulsive force for the virial expression is justified by the experimental result that adsorption of alkali metal atoms occurs strongly only when the electron affinity of the adsorbent metal exceeds the ionising potential of the alkali metal. The positive charge on the adatoms causes a change in contact potential by as much as 3 volts and a corresponding increase in electron emission. It is then shown that it is possible to calculate the moments M as functions of θ. In the case of cæsium on tungsten, these vary from 16 debyes for $\theta = 0$ to 6 debyes for $\theta = 0{\cdot}9$. The electron and positive ion emission rates are then calculated and found to be in agreement with experiment. In the first case, the influence of electron spin is taken into account and Dushman's equation, derived from the Sackur-Tetrode relation, is somewhat modified, although probably within the limits of experimental error.

The results on the evaporation of cæsium films are very different from those predicted by the old formula (2), based on the assumption that there are no repulsions between adatoms, but the general results are in agreement with the new equations.

The effect of inhomogeneity of the adsorbing surface, first predicted by Langmuir and since studied experimentally and theoretically by H. S. Taylor and others, is then considered. The importance of the so-called 'active areas' in determining the catalytic properties of surfaces, even plane surfaces, is well known. It is shown, however, that the calculations lead to the result that the tungsten surface is essentially homogeneous, although they indicate that on about 0·5 per cent of the surface the cæsium atoms are much more firmly bound than the rest. The active spots probably consist of isolated elementary surfaces each capable of holding one adatom.

University and Educational Intelligence

CAMBRIDGE.—The Busk studentship in aeronautics, founded in memory of Edward Teshmaker Busk, who lost his life in 1914 whilst flying an experimental aeroplane, has been awarded for the year 1932–33 to Mr. Herbert Brian Squire, of Balliol College, Oxford.

LONDON.—The Coal and Corn and Finance Committee of the Common Council of the Corporation of the City of London has recommended the grant of £100,000 towards the new central buildings of the University which are to be erected in Bloomsbury (see NATURE of July 9, p. 49). At Lord Macmillan's suggestion, the gift of the Corporation will be devoted

to the building of the Great Hall. The grant will be payable over a period of ten years, in annual sums of £10,000, commencing on March 25, 1933, and is conditional on the balance of the cost of the Hall being subscribed, and that the Hall shall be identified permanently and prominently with the Corporation. In a letter to the University, the Lord Mayor expressed the hope that the subscriptions towards the balance will help still further to identify the University with the City.

THE University of London has recently issued a prospectus of twelve courses of university extension lectures to be held during the session 1932–33 at various centres in London. The method adopted in such courses is to follow each lecture with a conversational class. Written work will be set, the submission of which will be optional, but regular attendance, etc., will entitle students to enter for an examination at the end of the course, in connexion with which certificates will be awarded by the University. The courses include the following: twenty-four lectures on "The Psychology of Everyday Life", by Prof. Cyril Burt, at Gresham College; ten lectures on "Religion and Science", by the Rev. S. C. Carpenter, at the Kingsway Hall; twenty-four lectures on "Problems of Society and Government", by Mr. A. Barratt Brown, at the Mary Ward Settlement. The first lecture of each course is free. Further information with regard to these courses of lectures can be obtained from the University Extension Registrar, University of London, South Kensington, London, S.W.7.

THE ninety-first session of the School of Pharmacy of the Pharmaceutical Society of Great Britain will open on Oct. 5, when the inaugural sessional address will be delivered by Dr. C. W. Kimmins, formerly chief inspector in the Education Department of the London County Council.

THE Royal Institute of Public Health has recently issued prospectuses of three courses of lectures and lecture-discussions to be held during the coming winter. The Harben lectures will be delivered on Oct. 10, 11, and 12, at 4 P.M., by Prof. Max Neisser, professor of bacteriology and hygiene at the University of Frankfurt-on-Main, on "Some New Investigations regarding Old Bacteriological Problems". A course of eight lectures, to be delivered by various lecturers, will be given on Wednesdays, commencing Oct. 19, on "Preventive Medicine: The Maintenance of Health and the Avoidance of Disease". Six lecture-discussions have also been arranged to take place on Thursdays, commencing Oct. 27, on "Mental Defectiveness as a Medico-Sociological Problem". All the lectures are free. Further information can be obtained from the Secretary, Royal Institute of Public Health, 23 Queen Square, London, W.C.1.

ERRATUM.—In NATURE of Aug. 27, p. 321, in the title of the thesis for the degree of D.Sc. (Engineering) conferred on Mr. C. E. Larard, the word 'their' should read 'other'.

Calendar of Geographical Exploration

Oct. 2, 1788.—Western Pacific Islands

Capt. John Hunter sailed to the Cape via the Cape Horn route. In 1789 he carried out surveys of parts of the coast of New South Wales and reached Norfolk Island, where his ship was wrecked. In March 1791 he sailed for Batavia and discovered the Stewart Isles and the Lord Howe Archipelago, the latter group being the Ontong Java named by Tasman. After passing the Admiralty group, Hunter discovered and named Phillip Island.

Oct. 5, 1876.—Records of an Arctic Winter

The crew of a vessel built and fitted out by a Russian, Sidoroff, who was interested in arctic navigation, began life in winter quarters at the Briochov Islands in the Yenisei delta, lat. 70° 48′ N. Nummelin, who was in charge of the expedition, with four exiles, kept temperature records from day to day and Nordenskiöld records his results in his account of the voyage of the *Vega*. Nummelin's four companions died of scurvy, but three others later joined him. A relief party came from the south on May 11 and tried to dig the vessel from the snow and ice, but it was again buried by a snowstorm. In mid-June the ice began to melt and the waters rose so high that Nummelin, with five men and two dogs and a small stock of food and fuel, had to pass six days perched on the roof of a hut. Night and day the men poled away the blocks of ice which threatened to crush the hut; on June 25 the water subsided and they were able to climb down.

Oct. 6, 1777.—The Orange River

R. J. Gordon and W. Paterson left Cape Town on a journey in which Gordon reached the Vaal. The two men afterwards made several journeys in different directions, which resulted in the survey of the lower course of the Orange River and in great additions to knowledge of the botany of the region. Paterson was particularly interested in natural history and obtained a valuable collection of South African plants.

Oct. 7, 1844.—From East Coast to North in Australia

Dr. Ludwig Leichhardt started from the Condamine River and reached the Gulf of Carpentaria. Leichhardt's aim was to find a route from the east coast of Australia to the north; in this he was successful, reaching Port Victoria in September of the following year. His journey covered 3000 miles, opened up valuable country, and added much to the knowledge of the orography and drainage of the region through which he passed. Leichhardt met his death two years later in an attempt to cross Australia from east to west.

Oct. 8, 1515.—Estuary of the Plate River

Juan Diaz de Solis sailed from the port of Lepe, reached the Bay of Rio de Janeiro on Jan. 1, 1516, and continuing southwards entered the great estuary of the Rio de la Plata. De Solis reached the north of the Parana River, but was there murdered by Guarani Indians. Sebastian Cabot explored the estuary in 1527 and ascended the Parana to the limit of navigation, the Agipe Falls. A Spanish expedition under Pedro de Mendoza landed in the estuary in 1535 and founded the city of Buenos Aires, but the hostility of the Indians caused the settlement to disappear. In 1541, Cabez de Vaca landed on the island of Sta. Catarina, reached the mainland, and by December 1541 arrived at the Iquassu, a tributary of the Parana, and thence took possession of the Parana for Spain. De Vaca rebuilt the port of Buenos Aires, and on a later expedition up the Paraguay reached the marshy country of Xarayes; he had previously explored the northern shores of the Gulf of Mexico (see Calendar for Aug. 10).

Societies and Academies

Cape Town

Royal Society of South Africa, June 15.—**D. Epstein**: The action of histamine on the respiratory passages. A method was described by which the effects of drugs on the isolated trachea and bronchi of small animals can be recorded with a magnification of about two hundred times. Using this method it was found that histamine produces powerful constriction of the trachea and bronchi of the guinea-pig, but has no effect on or relaxes these structures in the cat. As a result of other methods of investigation it was concluded that histamine produces obstruction of the air passages of the guinea-pig by a direct constrictor effect on the musculature of the trachea, bronchi, and probably bronchioles, while in the cat the respiratory obstruction seen with this drug is due to a constriction limited to the bronchioles alone. On the basis of these results, hypotheses have been put forward in an attempt to examine the respiratory reactions seen in anaphylaxis and asthma.—**H. A. Shapiro** and **H. Zwarenstein**: The effects of hypophysectomy and castration on serum calcium in *Xenopus lævis*. The finding of Charles that removal of both lobes of the pituitary leads to a significant drop in serum calcium is confirmed. Spontaneous partial atrophy of the ovaries in vlei females is found to be associated with a significant drop of 24 per cent. Castration of vlei females gives the same fall in serum calcium as double hypophysectomy, that is, about 40 per cent. This result can be detected as early as eleven weeks after the operation. In males a slight rise of 7·6 per cent, which is not significant, is observed after removal of both lobes. Castration leads to a significant drop of 14·6 per cent. It is probable that in females the drop after hypophysectomy is primarily due to ovarian atrophy.—**B. G. Shapiro** and **H. Zwarenstein**: The effect of injections of arginine and histidine on urinary creatinine. Injections of large doses of arginine or of histidine gives a 12-40 per cent increase in urinary creatinine. Alanine has no effect. After injection of Locke's solution as a control the creatinine excretion was unaffected.—**A. J. H. Goodwin**: Some developments in technique during the earlier stone age. It is suggested that the lower palæolithic of Europe presents only the beginning and the end of a single technical development, which is better represented as a complete series in Africa. Further developments are also suggested as being represented by the Mousterian and the Grand Pressigny techniques.

Geneva

Society of Physics and Natural History, June 16.—**R. Wavre**: Newtonian potential and topology. The author raises the question under what conditions two families of bodies can create the same potential in a certain domain, and shows the importance of the topological distribution of the bodies investigated.—**F. Vasilesco** and **R. Wavre**: Simple examples of multiform harmonic functions. This note establishes that any homogeneous spherical cap produces a Newtonian potential which is an element of a multiform harmonic function. The latter allows an infinity of determinations which ramify round the frontier line of the cap. There is no other singularity of the function, except this: the period function admits a pole at the centre of the sphere.—**E. Friedheim**: The respiratory function of the pigment of *Bacillus violaceus*. The author's experiments lead to the conclusion that the pigment of the violet bacillus accelerates respiration by acting as a hydrogen acceptor. It is not yet proved that it acts as a perfect catalyst regenerated during a cyclic process.—**G. Tiercy**: A historical note. The hypothesis of continental translations. The author points out that the hypothesis of continental translations was formulated by Snider in 1858 and by Père Placot in 1668. Without disregarding the value of Wegener's work, M. Tiercy considers that it is inexact to describe the hypothesis in question as Wegener's hypothesis.

Sydney

Linnean Society of New South Wales, April 27.—**Mary E. Fuller**: The larvæ of the Australian sheep blowflies. The following species are described: *Calliphora stygia* Fabr., *C. fallax* Hardy, *C. augur* Fabr., *Lucilia sericata* Mg., *L. cuprina* Wied., *Chrysomyia micropogon* Bigot, *Ch. rufifacies* Macq., *Microcalliphora varipes* Macq., *Sarcophaga* sp., *Peronia rostrata* A.D., *Ophyra nigra* Macq. A key is included by which these species may be recognised in the larval stage.—**J. R. Malloch**: Notes on Australian Diptera. Notes on species of the genera *Calliphora* (of which three species are described as new) and *Onesia* are given. A key is given for the determination of males of species of *Calliphora* related to *C. stygia*.—**H. Womersley**: A preliminary account of the Protura of Australia. A classification of the order is given, followed by descriptions of the Australian species, which consist of four new species of *Acerentulus* and two of *Eosentomon*.—**J. Andrews**: Rainfall reliability in Australia. Rainfall reliability is principally concerned with the amount of rain which might be expected during any season and the degree of probability of obtaining it. These two aspects of reliability are discussed on the basis of annual figures and for the continent of Australia as a whole.—**F. A. Craft**: Geographical studies in the Blue Mountain Tableland. In the Blue Mountain Tableland settlement is almost confined to the main route passing westward from Sydney to the interior, along which towns and villages have grown since the building of the Western Railway. Some of these depend on the tourist traffic, whilst others support mining and industrial populations. The higher tablelands are barren, but the valleys of the Cox and lower Wollondilly Rivers are used for grazing, and restricted bottoms for agriculture.—**W. L. Waterhouse**: On the production in Australia of two new physiological forms of leaf rust of wheat, *Puccinia triticina*. As a result of inoculating plants of *Thalictrum flavum* and *T. dipterocarpon* with a mixture of germinating teleutospores of the forms of *Puccinia triticina* designated 'Australian 1' and 'Australian 2', æcidia were produced. Uredospore cultures from these showed that three physiological forms were present. One was the form 'Australia 1', but the other two have not been previously found. Details of their reactions were determined. These new forms originated on the alternate host plant, most probably as the result of hybridisation of the forms 'Australian 1' and 'Australian 2'.

Vienna

Academy of Sciences, July 7.—**Richard Weiss** and **Alfred Abeles** (with Ernest Knapp): Condensation of $\alpha\alpha'$-diphenyl-$\beta\beta'$-benzofuran with unsaturated compounds. (2) 1 : 4-Diphenylnaphthalene and its derivatives.—**Anton Kailan** and **Paula Ulicny**: Ester-formation in glycerol and ethyl alcohol. The unimolecular velocity constants (k) for the esterification of n-valeric, caproic, caprylic, and i-valeric acids at 25°, catalysed by c molecules of hydrogen chloride per litre, in glycerol with a mean water content of w mol. a litre, are represented by equations of the form $c/k = \alpha + \beta w + \gamma w^{3/2}$. For the esterification of o-, m-, and p-toluic acids by alcoholic hydrogen chloride, the velocity constants are represented by a more complicated

expression; comparison of the results with those given by benzoic acid shows that the methyl group introduced has the greatest retarding effect in the ortho- and the least in the meta-position.—**Ernst Beutel and Artur Kutzelnigg**: (1) The possibility of following the recrystallisation of silver by coloration with iron chloride.—(2) Properties of silver chloride films formed by the action of iron chloride on silver surfaces.—**Alexander Köhler and Hans Leitmeier**: Thermoluminescence in minerals. The luminescence of a large number of minerals heated to 250°-350° on an earthenware or asbestos plate has been examined. The results differ markedly in some respects from those of previous investigators, no luminescence being shown, for example, with sulphides, tinstone, etc.—**A. Schedler**: Magnetic declination in Austria, Bohemia, Moravia, and Silesia. The results of investigations on the earth's magnetism in Central Europe during recent years are used to obtain a general view of the distribution of magnetic declination throughout Austria and parts of Czechoslovakia.—**Wilhelm Kühnelt and Ekkehard Schmid**: Conditions of life at the snow line of the upper Alps.—**Friedrich Querner**: The paraplasmatic inclusions of liver cells in the fluorescence microscope, and the luminous material. When subjected to the action of ultra-violet light of wave-length 4000-3000 A., the liver cells of various vertebrates, including man, exhibit striking fluorescence.—**Adolf Müller and Paul Krauss**: (1) Synthesis of ε-amino-*n*-heptoic acid. This synthesis was realised by the reduction of the phenylhydrazone of ε-keto-*n*-heptoic acid.—(2) 2-Methylhexamethylenimine. The constitution of this compound is confirmed by (*a*) its synthesis from ε-amino-*n*-heptoic acid via the lactam, and (*b*) by oxidative scission of *N*-benzenesulphonyl-2-methylhexamethylenimine to the corresponding derivative of ε-amino-*n*-heptoic acid.—(3) The action of alkali on 6-bromo-*n*-hexylamine and on 7-bromo-*n*-heptylamine. With the bromohexylamine only a small proportion of the 7-membered cyclic hexamethylenimin is formed, and with the bromoheptylamine, the formation of an 8-membered ring is not detectable.—**Georg Koller**: Ramalic acid. It is shown that ramalic acid, reported by Hesse (1861) and Zopf (1897) as occurring in *Ramalina pollinaria*, does not exist.—**Otto Brunner, Hanns Hofer, and Rosa Stein**: Amyrins. (2) Products of dehydrogenation by selenium. Further proof that amyrins belong to the triterpenes is obtained.—**Karl Morsch**: Action of ammonia and amines on the esters of unsaturated acids. (2) The action of ammonia, methylamine, and diethylamine on ethyl cinnamate.—**Herbert Haberlandt**: Microscopic investigation of a Morogoro mineral in incident light.—**Elisabeth Rona**: Evaporation experiments with polonium.—**Adelina Deseyve, Gerhard Kirsch, and Fritz Rieder**: Disintegration of the atom by neutrons. Experiments with a number of elements by the scintillation method are described.—**Marietta Blau and Hertha Wambacher**: Attempts to reveal photographically protons liberated by neutrons. These attempts have not yet been successful.—**H. K. Barrenscheen, Wilhelm Filz, Karl Braun, Konrad Müller, and Sándor Láng**: Chemistry and physiology of the adenosintriphosphoric acids. A constitutional formula is given for the adenosintriphosphoric acid discovered by Lohmann and simultaneously by Fiske and Subbarow.—**Rudolf Wagner**: *Ardisiandra Wettsteinii* n. sp.—**Robert Kremann and Robert Baum**: The galvanic potentials and constitution of gold amalgams. Amalgams containing less than 75 per cent of gold show the mercury potential, and those with higher proportions of gold, the gold potential. Only those poor in mercury are, therefore, resistant; the resistance limit corresponds approximately with the compound Au_3Hg, for which Pabst found a hexagonal lattice structure.—**Franz Griengl and Robert Baum**: Galvanic potentials of ternary gold-tin-mercury alloys. The potential-concentration curves of the three binary systems and of a number of ternary mixtures show that, in the mercury phase, the compounds AuSn and $AuSn_2$ must be dissociated.—**Ludwig Lämmermayer (jun.) and Robert Kremann**: The position of gold in the potential series of the electrolysis of molten alloys. In its alloys with bismuth, antimony, and lead, gold migrates to the cathode, whereas in those with aluminium virtually no displacement of concentration occurs. In the potential series, gold probably stands near to silver.—**Robert Kremann, Max Pestemer, and Paula Bernstein**: Ultra-violet absorption by binary liquid mixtures. (1) The system chloroform-acetone. In these mixtures the maximum of the acetone absorption band is raised appreciably, whilst the chloroform band is only slightly displaced. A faint band, corresponding with the compound of the two solvents, also appears.—**A. Dadieu, K. W. F. Kohlrausch, and A. Pongratz**: Raman effect. (23) Raman spectrum of polysubstituted benzenes. Of the two benzene frequencies, $\Delta v = 1000$ and 1600, the former is absent from the Raman spectra of all chloro-substituted benzene derivatives except the monochloro-, *m*-dichloro-, and *s*-trichloro-compounds. This frequency hence belongs to a form of vibration at which the molecule pulsates and has, not hexagonal, but trigonal symmetry, and either has or can form nodes at the 1-, 3-, and 5-positions; such symmetry must be ascribed to benzoic itself. The frequency $\Delta v = 1600$ is continually displaced to lower values as the loading of the molecule with chlorine increases, and for C_6Cl_6 reaches the value 1510. In this case the vibration is such that the atoms move almost tangentially in the plane of the ring; this vibration must disappear in a five-membered ring, but reappear in naphthalene, assuming the symmetrical form for the latter.—**Hans Lieb and Miloš Mladenović**: α-Elemol and elemonic acid.—**O. Aluta**: Culture experiments with *Arabis hirsuta* (L.) Scopoli.—**Th. Pintner**: Structures in *Tetrarhyncus* heads.—**Herbert Schober**: A highly sensitive photometer.

WASHINGTON, D.C.

National Academy of Sciences (*Proc.*, **18**, 343-408, May 15).—**G. A. Lebedeff**: Interaction of ruffled and rounded genes of *Drosophila virilis*. The gene for the character ruffled is normally recessive; in presence of the dominant gene for rounded wings, ruffled becomes dominant, producing a new character, roofed, which shows both the original characters in modified form.—**M. Louise Schmuck and Chas. W. Metz**: The maturation divisions and fertilisation in eggs of *Sciara coprophila*, Lint. Sperms in this species receive more than the haploid number of chromosomes; elimination seems to occur during differentiation of soma from germ-line.—**Anne Marie Dubois**: Elimination of chromosomes during cleavage in the eggs of *Sciara* (Diptera).—**B. R. Nebel and Iris J. Trump**: Xenia and metaxenia in apples (2).—**Willem J. Luyten**: Notes on stellar statistics (5). On the use of the first Laplacean error curve.—**John S. Hall**: The application of photoelectric cells sensitive in the infra-red to stellar photometry. Cæsium oxide on silver photocells cooled with 'dry ice' was used. Cooling reduces the current passing when no visible radiation falls on the cell to the limits of sensitivity of the galvanometer used, stabilises the photo-current, and apparently raises the glow potential. In practice the photoelectric current is nearly proportional to the incident light intensity over the range of stellar

magnitudes extending from 3·0 to 6·5 and gives reproducible results.—**G. H. Dieke** and **G. B. Kistiakowsky**: The rotational structure of the ultra-violet absorption bands of formaldehyde. Photographs were taken in the third order of the 40-ft. spectrograph of the Loomis Laboratory, giving a dispersion of 0·4 A. per mm.—**P. S. Crowell**: The ciliation of the oviducts of reptiles. In two lizards examined, there is a tract of cilia in the albumen-secreting region of the oviduct which probably convey sperms up the oviduct.—**S. C. Lind** and **Charles Rosenblum**: The combination of carbon monoxide and oxygen under the influence of radon. Carbon dioxide promotes the reaction, but only about 14·5 per cent of the ionisation is chemically effective. The recoil atom effect and the inverse square of the diameter law were also examined.—**Ernst Cloos**: 'Feather joints' as indicators of the direction of movements on faults, thrusts, joints, and magmatic contacts. These local joints are so named because they are arranged like the barbs of a feather; they frequently appear along boundaries of moved blocks, etc., and their position and direction indicate the nature of the movements which have taken place. Circular impressions were made on wet clay placed on two iron plates resting side by side. On moving one plate, the impressions are deformed, indicating the axis of strain, and tension joints, shear joints, etc., are formed. Parallel effects are observed in the field, suggesting that such laboratory experiments are useful imitations of natural conditions.—**Charles N. Moore**: On certain criteria for Fourier constants of L integrable functions.—**I. A. Barnett** and **David Nathan**: Sphere geometry and the conformal group in function space.—**J. H. Roberts**: Concerning unordered spaces.—**J. Karamata**: Remarks on a theorem of D. V. Widder.

Forthcoming Events

MONDAY, OCT. 3

ROYAL SOCIETY OF ARTS (Special Meeting).—Robert Howden: "The Elimination of Reflections from Glazed Pictures in Galleries", at 3 P.M.

SOCIETY OF CHEMICAL INDUSTRY (Chemical Engineering Group, jointly with the London Section) (Jubilee Memorial Lecture).—Dr. G. D. Bengough: "The Corrosion of Metals in Salt Solutions and Sea-Water", at 8 P.M.

TUESDAY, OCT. 4

INSTITUTION OF HEATING AND VENTILATING ENGINEERS (Autumn Special Meeting).—Dr. H. M. Vernon: "The Measurement, in Relation to Human Comfort, of the Radiation Produced by Various Heating Systems", at 6.45 P.M.

WEDNESDAY, OCT. 5

SOCIETY OF PUBLIC ANALYSTS (Joint Meeting with the Food Group of the Society of Chemical Industry, at the Chemical Society's Rooms, Burlington House, Piccadilly, W.1).—Discussion on "The Changes in Fruit on Storage", at 8 P.M.

FRIDAY, OCT. 7

PHYSICAL SOCIETY (at the Imperial College of Science and Technology, South Kensington).—Dr. J. W. French: "The Manufacture of Optical Glass", at 5 P.M.

Official Publications Received

BRITISH

Air Ministry: Aeronautical Research Committee: Reports and Memoranda. No. 1488: Corrosion Fatigue Test on Aluminium Crystal. By Dr. H. J. Grant and D. G. Sopwith. Pp. 30+12 plates. (London: H.M. Stationery Office.) 2*s.* 6*d.* net.

Ottawa and After

THE Ottawa Conference has been a success: how great a success it will be for posterity to decide. There were many who seriously believed that its failure would inevitably mean the break up of the British Empire. This view, indeed, was frankly stated at Ottawa, and it is a significant fact that almost everyône there was concerned to make every possible sacrifice to prevent such an eventuality. That particular danger, real or imaginary, is past, and there exists instead a definite acceleration of the Empire spirit, which is soon to be translated into action both in the mother country and in the Dominions.

Perhaps—nay, we would rather say definitely—this Ottawa spirit is of even greater value than all the practical concessions and agreements. It is for every Briton to foster and develop it to the advantage of all parts of the Empire. The Dominions are to-day equivalent to full-grown men and are no longer in the stage of infant colonies to be watched over with navy and army and lent a machinery for government: those who have not visited and spent some time in the Dominions fail very largely to understand that they are nearer the realities of life as enforced by climate, by long distances between towns, and by a spirit of democracy and freedom. The standard of living in the Dominions is higher, though their standard of culture may be less, than in England. In short, their habits in many respects are not the same as ours. We cannot change them, and therefore the mother country must study them and sympathise with them if we essay to sell to them our manufactured articles.

The details of the arrangements made at Ottawa between Great Britain and the Dominions have not yet been divulged, but it is known that they include substantially increased British preference by the Dominions on a very large number of articles, sufficient to place us in a most favourable position in competition with foreign nations, together with an amelioration of Customs regulations and the like.

In very general terms it was possible to distinguish at Ottawa between a background of experts and industrial representatives and a foreground of politicians. The former were engaged in surveying fields of industry, in establishing facts, in making contacts, in bringing into being potential agreements up to the point of signature.

They created an atmosphere which might almost be described as scientific in its attitude, and it is not impossible to conceive that had they been given plenary powers many fair and wise and acceptable understandings could have been implemented without difficulty, and that even the points of disagreement, when once tabulated, could have been reduced to a minimum. The political atmosphere was of another kind. The item of bargaining had been introduced, and all those other factors which constitute what is called politics and are responsible for so much of the crazy anomalies of the present world.

It is difficult for people engaged in scientific pursuits to understand why membership of a political party, largely for hereditary reasons, makes the individual resolutely shut his mind to facts or consequences and impels him to work for a traditional policy, without reference to its merits or demerits, its repercussions on himself, his family, his friends or his country, or civilisation at large. The world is in labour: sacrifices are necessary from everyone: old policies have failed: new ones must be investigated. It may even be that the day of the individual has passed. Governments to-day listen only to associations, whether they be large bodies of voters or organised associations representing traders. No one individual or firm can be allowed to sacrifice the community to personal ends. Limitation of personal output as practised by the trade unions has few defenders, but limitation of production has been held up as a solution of the economic crisis, and will be again, though it has been tried and has failed this time. It is not enough to limit production: a check must also be placed on the uncontrolled extension of the capacity to produce. A new invention, a new method of making something results in the erection of a factory to make an article, in spite of the fact that the existing factory or factories are fully able to meet the demand. The new nationalism, one of the worst diseases resulting from the War, has caused every country to engage in manufacture for itself, largely unnecessary, often uneconomic and only existing as the result of tariffs. Hence the destruction of international trade, the cessation of exports, the disturbance of the channels of credit, the upset of exchange, and the inevitable unbalanced budgets.

Reason must prevail if we are to return to normality. There must be some agreement to restrain the erection of new factories or the enlargement of old plants, when abundant up-to-date capacity for production already exists. There are already examples in Great Britain of restricted industries which are half monopolies, and which can only extend at the will of Parliament and after relevant opposition has been heard. Such is the gas industry, which offers continuous and regular employment, with pension privileges, to its staff and workpeople, and yet is technically and commercially abreast of the times. A local gas company is still in the fiercest competition with electricity and oil, but it is spared, however, competition with another gas works in the vicinity which, if allowed, would reduce both factories to fifty per cent load, with evil consequences to half the staff of each, and imperil the economic future of both concerns. A synthetic ammonia works has no such protection against duplication of production, and unreasoning competition, yet the provision of fertilisers is an essential national industry, which should be capable of being stabilised.

We have strayed from the subject of Ottawa, but such ideas as are contained in the above were under discussion there, if only in the background. Canada, Australia and South Africa are determined to have certain manufacturing industries, but before venturing into what are for them new fields of industrial activity, they are prepared to ask the question—Is it economic? It is here that the mother country has an opportunity, if we are willing to profit by the spirit of co-operation with our fellow Britons.

There are factories enough in England: the Dominions will give us ample preference for their manufactures. It remains to get together to ascertain the needs of the Dominions, satisfy them as to price, quality, time of delivery—above all, give to them, the buyers, all that is understood in the term 'sales service', which is a word scarcely known in its true sense in Great Britain but which is the key to commercial success across the seven seas. Only in this way can we prevent in the future the erection of unnecessary new factories within the Empire, though at the same time we must take care at home, through our trade organisations or, failing them, our Government, that unnecessary factories are not built here either. The day has come when the industrial worker can and will claim some measure of stability in his employment and not allow the industry which supports him to be at the mercy of the adventurer or the foreigner.

The Dominions are alive to the need for education—schools, universities, training colleges, research institutions exist, if anything, ahead of the needs of the population, and it is partly the attractions of an outdoor life in a superior climate which retard the spread of higher culture in home life. What the Dominions need more than anything else if they would have a real regard for the future is to attract and retain the very best first class men possible for their university professorships. Many such men have been there in the past and some are there at present, but there is need and room for more. The Dominions are but sparsely populated with picked men and women; they must pick their leaders too, and they can afford none but the best.

Biological Teaching

(6) *The Essentials of Biology*. By Prof. James Johnstone. Pp. xv + 328. (London: Edward Arnold and Co., 1932.) 16*s*. net.

IT is not many years since biology teaching in schools, with very few exceptions, was practically confined to the top form and then was only provided for boys who intended to become medical men. Possibly a little nature study or even botany was taught in the lower school but anything in the nature of a continuous course in natural science throughout the school such as has been planned for mathematics or the literary subjects was not thought of. Even now a course of science in which biology plays a part commensurate with its importance to man is a dream of the future. However, a change has come over the scene, and an indication of it is the fact that all the university examining bodies, in deference to a popular demand, have provided syllabuses in biology for the School Certificate examination.

This is a step in the right direction. All the hard words which are uttered against examinations do not obscure the reason for which they exist, namely to afford some indication that candidates are acquiring sound knowledge and a broad view of their subject; and the syllabus for this examination is drawn up with this end in view. The syllabuses for School Certificate biology are all modifications of the 'type system'; that is, by examining in some detail a number of organisms the essential unity of life as well as a little of the diversity of organic beings becomes apparent. So in the book before us—"Fundamentals of Biology" (1)—an account of the anatomy and physiology of a single vertebrate animal, man, and the flowering plant form the central part of the book, and starting from this basis a survey of the animal and plant kingdom is taken, not very full but enough to give some idea of the evolution of the vertebrates and the land plants. While practical work cannot be insisted upon to the same extent as in post-Certificate work, it is regarded as important that a knowledge of the type shall be obtained by direct observation, and this involves, at any rate, an inspection of dissections of animal types (the frog, the earthworm and the cockroach) which have been made for the class by the teacher. Also a knowledge of the functions of organs is fostered by encouraging the staging of simple physiological experiments in class. Examples of such experiments are cited at the end of the chapters: the development of this side of biology teaching will contribute very largely to its success.

A very elementary introduction to the use of the microscope may be made at this stage. The study of *Amœba* and *Hydra* is prescribed but it must be realised that in many schools there are not enough microscopes for the needs of large classes, and in nearly all, the exigencies of the timetable do not allow enough time for the cultivation of the patience necessary for microscopic work in boys and girls of the Certificate age. Lastly should be mentioned the part which the 'natural history' of animals, or the 'associations' of plants, may play in the early stages of biological education. Little equipment is needed for these branches of study

but a good deal of time outside regular school hours. Unfortunately compulsory games and other occupations claim so much of a boy's leisure that he must be a 'red-hot' enthusiast to pursue the study of field work, and this is why the part of syllabuses which deals with it only appears in examination to have been covered by isolated individuals.

From what has been said it will be seen that the teaching of biology to boys and girls between say fourteen and sixteen years of age is on a period of trial. Though the framers of syllabuses have agreed wholeheartedly to embrace the type system the treatment by the teacher must be very different from that necessary in the case of the post-Certificate student, and for that reason the writing of a textbook by an author who has already had experience is exceedingly welcome. Mr. Stork is a master at Charterhouse, where under O. H. Latter so much spadework in the service of biological teaching has been done. The result of his collaboration with Prof. Renouf is a very useful book which contains, besides the clear exposition of the main theme, admirably illustrated by drawings which are largely new, a number of appendixes. Of these, one contains a number of very elementary facts about chemistry and physics which may be useful to beginners in science, a second deals with such practical things as the source of supply of material for classes and the making up of various solutions, and a third gives a number of questions which have been set in School Certificate and Matriculation examinations. In conclusion, one criticism may be perhaps made—that the book might be a little shorter and less packed with fact, with advantage to most students.

(2) The general character of the next examinations in biology, namely, those for the Higher Certificate and the First M.B., is the same for all the examining bodies. The student deals with a larger series of types with more or less thoroughness. What is, however, a desperate affair for the schoolmaster, who has in his class candidates who are going to several universities and medical schools, are the minor variations in the syllabuses, especially where types are concerned. It is earnestly to be desired that the English examining bodies at least should agree upon a list of identical animal and plant types, nor could such an agreement possibly interfere with the general efficiency of the examination. Thus "Biology for Medical Students" is written for the examinations of the University of London and the Conjoint Board. There are so many excellent textbooks which cover almost the same field, that a newcomer must expect critical examination. The authors point out that in most cases separate textbooks in zoology and in botany are recommended at this stage, a division which is also seen in the teaching of biology in separate zoological and botanical departments. However, the duplication of teaching becomes increasingly difficult to avoid, and probably the best that can be hoped for is for botanists and zoologists to collaborate as closely as in the present case. This book has much to recommend it. The descriptions are clear and the illustrations are excellent, particularly in the botanical part where many microphotographs have been utilised. There is a very good section on embryology, concise and yet comprehensive. Still there is nothing very distinctive about the method of treatment while recent research does not always receive its due meed. In *Paramecium*, for example, the rôle of the trichocysts is quite other than that suggested here, and surely the assumption that the contractile vacuole is a mechanism directly concerned with the rate of katabolism has no foundation in experiment. It has often been pointed out, on the other hand, that it is primarily an organ regulating osmotic pressure.

(3) Prof. Woodruff's "Animal Biology" is a version of his well-established textbook, "The Foundations of Biology", designed "for courses in animal biology and general zoology in which plants are considered only incidentally in their relations with animals". It deals with general biology and so must be read with a book which supplies "the details of morphology and physiology of selected types as well as direction for their study in the laboratory". It is in fact the complement of the last-mentioned book. It has many excellent points. The reviewer, however, cannot help thinking that the survey of comparative anatomy and the morphological distinctions of the animal groups is too superficial even at this stage. The sections on development, inheritance and organic adaptation are, however, admirable.

(4) Prof. Van Cleave in his "Invertebrate Zoology" demonstrates very clearly how difficult it is in a book of 280 pages to give an adequate idea of the comparative morphology and relationships of the various 'invertebrate' groups. To take the Coelenterata as an example, while there is a formidable classification at the end of the chapter no clear idea of the difference between polyp and

medusa is given, of the methods of skeleton formation throughout the phylum or even the structure of the threadcell. The reviewer can find little to recommend this book.

(5) There is no doubt as to the importance of including embryology in a general biological course. A general knowledge of the development of the frog and the chick at least ought to be obtained by zoological students, the foundations being laid in the Higher Certificate or First M.B. part of the course and built upon during work for the university degree. Prof. Mary Harman in her "Textbook of Embryology" has written a handy volume, well planned and carried out, and full of useful detail. It deals principally with mammalian embryology and especially human development and should be of value as a book of reference to zoological students. It is, however, rather surprising to learn that the author is accustomed to use the material of this book in her lectures to students in home economics and physical education and "those taking embryology as a cultural subject".

(6) Prof. Johnstone's remarkable analysis of biological data and theory is a book of a very different category from those which have been mentioned above. The field which is surveyed is so vast and the survey is so concisely worded that a student who attempts to use it must have a good deal of previous knowledge, and certainly have experienced some of the "discipline of practical laboratory work on animal types". The 'non-professional' reader could scarcely be satisfied by the meagre summary account of animal morphology which is given. But for a thoughtful undergraduate who wants to take stock of his knowledge of zoology and the place which the science occupies amongst its sisters we cannot too strongly recommend this lucid statement of progress, which contains compressed into less than 300 pages a discussion of zoology in all its bearings. Prof. Johnstone's own points of view with regard to biological theory are indicated in the introduction. "Not only the 'Weismannism' of a former generation, but also the 'Morganism' of to-day have proved unsatisfactory." His hopes for the future are expressed there likewise. "A survey of biological science gives us certain indications that its growing point, at present, is in biochemistry and that this growth of significant theoretical knowledge will be accelerated when it will have been possible to press new physical results into the service of biology."

History of Public Health

(1) *Towards National Health: or Health and Hygiene in England from Roman to Victorian Times.* By J. Anthony Delmege. Pp. xiv + 234. (London: William Heinemann [Medical Books] Ltd., 1931.) 21*s*. net.

(2) *Devils, Drugs and Doctors: the Story of the Science of Healing from Medicine-Man to Doctor.* By Prof. Howard W. Haggard. Pp. xxii + 405 + 16 plates. (London: William Heinemann [Medical Books] Ltd., 1931.) 21*s*. net.

HERE are two attractively written and generously illustrated volumes by an Englishman and an American respectively, which form an excellent introduction to the history of medicine in general and of public health in particular.

(1) Dr. Delmege sets out to trace the development of those factors which influence most directly communal health, and surveys those changes in scientific knowledge which have brought about the formation of sound hygienic principles and their practical application to our national life. His work is divided into six chapters dealing respectively with hygiene in the early civilisations, the Dark Ages and the Middle Ages, the sixteenth, seventeenth and eighteenth centuries, and the period 1800–75, the date of the passing of the great Public Health Act.

In his first chapter Dr. Delmege gives a short survey of public health in ancient Crete, Egypt, Palestine, Greece, Rome and Roman Britain. In spite of the baneful effect of medieval Christianity on hygiene, the Dark Ages, by way of compensation, are shown to be responsible for the erection of hospitals, homes for the aged, orphanages and foundling homes, and the establishment of nursing confraternities. In the sixteenth century the State relief of pauperism, which had hitherto been left to private charity, began to develop in Britain, and more attention was paid to personal hygiene, especially by the upper classes, but the sanitary condition of the streets in London and the other large towns was deplorable.

In the seventeenth century urban conditions still remained very largely medieval, but certain diseases such as plague and leprosy which had been prevalent in the Middle Ages, died out, and syphilis was no longer epidemic. Smallpox, however, was assuming an epidemic form and outbreaks of scarlet fever and measles were occurring.

In spite of peace and general prosperity during the eighteenth century, the health of the people

was bad during the first fifty years, but afterwards showed considerable improvement as the result of better urban sanitation and vigorous efforts to prevent the spread of typhus fever as well as attention to maternity and child welfare. Owing to widespread scarcity and poverty, the social conditions of the first half of the nineteenth century were by no means favourable to health and sanitary reform, but thanks to the work of Shaftesbury, Chadwick, Southwood, Smith, John Simon and others, important reforms in public health including the training of nurses, inaugurated by Florence Nightingale, were introduced.

The diseases prevalent in each of these periods are noted, and a description of each is given in an appendix for the benefit of the lay reader. Another appendix contains a table showing the dates of the principal events in the history of hygiene from the third to the nineteenth centuries.

The text is accompanied by contemporary illustrations of various buildings connected with sanitation such as hospitals, dwelling houses of different types, sewers, aqueducts and baths, and portraits of eminent physicians and sanitary reformers.

(2) Dr. Haggard's work, the unconventional and lively character of which is indicated by its title, is divided into six parts. Part I, which is entitled "The Conquest of Death at Birth", deals with the progress of midwifery throughout the ages, with illustrations of childbirth in ancient Greece and Rome, the Middle Ages and savage tribes, the story of the midwifery forceps, and the campaign against puerperal fever. Part 2, which is devoted to the history of anæsthesia, contains an account of the discoveries in this field of Sir Humphry Davy, Horace Wells, William Morton and Sir James Young Simpson.

Part 3, in which the progress of surgery from the earliest times until the present day is considered, is divided into two chapters, the first dealing with the study of anatomy and particularly the difficulty in obtaining bodies for dissection, and the second with the work of Ambroise Paré, the introduction of the trained nurse, and the change in surgery caused by the discoveries of Pasteur and Lister.

Part 4, which is entitled "The Passing of Plague and Pestilence", consists of four chapters, the first of which contains the history of the Black Death, the second deals with smallpox and cholera, the third with syphilis and the fourth with the problem of prostitution.

Part 5 contains five chapters dealing with various modes of treatment of diseases including not only scientific methods such as those of Pinel, Pasteur, Behring and Ehrlich, but also different forms of quackery and faith-healing from the earliest times until the present day. In Part 6 the debt which civilisation owes to medicine is illustrated by numerous striking examples.

As in Dr. Delmege's work the text is freely interspersed with numerous well chosen contemporary illustrations.

French Colonial Ethnology

(1) *Notes d'Ethnologie Néo-Calédonienne.* Par Maurice Leenhardt. Pp. ix + 340 + 36 planches. 120 francs.

(2) *Documents Néo-Calédoniens.* Par Maurice Leenhardt. Pp. iv + 514. 125 francs.

(3) *Les Tribus du Rameau Lobi.* Par Prof. Henri Labouret. Pp. vii + 510 + 31 planches. 150 francs.

Université de Paris : Travaux et Mémoires de l'Institut d' Ethnologie. Tomes 8, 9 et 15. (Paris : Institut d'Ethnologie, 1930, 1931.)

ATTENTION has been directed from time to time in the columns of NATURE to the excellent work on matters of ethnological interest which is being done through its publications by the Institut d'Ethnologie of Paris. The works here under notice deal, on rather broader lines than the publications hitherto noticed, with peoples in two widely separated areas of the French colonial possessions.

(1) In "Notes d'Ethnologie Néo-Calédonienne", the author, a member of the Evangelical Mission of Paris who has lived in New Caledonia for twenty-five years, gives a great deal of valuable and welcome information relating to the sociology and religion of the people. Attention may be directed in particular to his account of the *pilou pilou*, the most important ceremony in the life of the people, involving preparations lasting more than three years, which has not hitherto been recorded in such detail as it is here. Other matters with which the author deals at length are the houses, currency, warfare, initiation, totemism, in which the totem of the mother is all-important and that of the father has no part, magic and the gods.

(2) M. Maurice Leenhardt follows up his study of the customs of the New Caledonians with a

collection of traditions and folk-tales. The original text is given with an interlinear translation and a free translation at the foot of each page. The author has annotated the tales fully with notes which expound the text where necessary and explain the allusions. The value of these annotations is considerable as these tales, more than most, contain allusions which would escape the notice of all but those who have a close acquaintance with custom and practice, as well as mode of thought. The author points out that it is an indication of the growing decay of tradition that in the later narrations, the teller of the tale inserts explanations of obscure expressions for the benefit of the younger generation.

Among these tales, those which the author groups as a lizard-totem cycle seem to belong to a remoter stratum of tradition; while those dealing with matrimonial infelicities, with the aid of the author's notes, throw some interesting sidelights on native mentality, such as, for example, in the resort to suicide as a method of retaliation through the spirit thus disembodied. The attitude of mind attributed to the wife who resents the adultery of her husband on the ground that he might thereby do harm to the ancestral element in her body is significant.

(3) In this volume M. Labouret has embodied the results of eleven years of observation among the Lobi, which began with his appointment in charge of the administrative district of Diébougou in French West Africa. It is a record of exceptional value, for as the author explains in describing his method of working among the natives, a great part of the material is recorded virtually by the natives themselves.

M. Labouret has been very thorough in the range of his observations, for there would appear to be very little in the life of the peoples that he has not covered. He begins with their history and then proceeds to the technology, arts, the social organisation, economics, law and morality, religion and magic. He confines himself, in the main, to a record of fact, without any attempt at cultural analysis; but he suggests tentatively that the Lobi, who live on the upper waters of the Volta in the south of the Cercle de Gaoua, may be a part of the great culture area which extends from the Bauchi plateau of Nigeria to Sikasso in the French Sudan. This is a culture of agriculturists, of which the common characteristics are absence of clothing for both sexes, the use of the labret among the women, a special type of rectangular dwelling and a common technique in metal working and pottery making (including a knowledge of the *cire perdue* process in casting), a village organisation, religious and secret societies, the use of poisoned arrows and a knowledge of the bull-roarer. The volume is illustrated by a long series of excellent plates.

Short Reviews

A Manual of Embryology: the Development of the Human Body. By Prof. J. Ernest Frazer. Pp. viii + 486. (London: Baillière, Tindall and Cox, 1931.) 30*s*. net.

FOR a quarter of a century Prof. Frazer has devoted himself to an intensive study of human embryos and from time to time has published brief accounts of special investigations, more especially on organogeny. He has now rendered a great service to anatomists and students of embryology by providing this full report on his life's work. It is a very personal record, for Prof. Frazer does not pretend to review the literature or make references to what others have done.

The interest and value of the book depend on the fact that it is a detailed report of what the author himself has seen in actual human embryos, illustrated by his own drawings. It is a great record of minute and prolonged observation.

So this is Science! By H. F. Ellis. Pp. x + 109. (London: Methuen and Co., Ltd., 1932.) 5*s*. net.

BOTH wit and humour are to be found in the travesties of scientific description included in this book. Mr. Ellis evidently knows something about scientific subjects and people, and is ingenious in presenting them in new and unexpected aspects; such, for example, as his definition of the stratosphere—"Said to be full of balloons hoist with their own Piccard". His clever play with words, and his inversion of ideas, make science laughable rather than ridiculous. Many college magazines have, however, contained contributions in similar style; and some of the Red Lion dinners of the British Association have provided burlesques just as amusing as any to be found in this book. Whether scientific readers will consider the hour's entertainment which it offers to be worth five shillings is another matter

Water Diviners and their Methods. By Henri Mager. Translated from the fourth edition of "*Les Sourciers et leurs Procédés*" by A. H. Bell. Pp. xi + 308 + 8 plates. (London: G. Bell and Sons, Ltd., 1931.) 16*s*. net.

THE origin of the divining rod is lost in antiquity, and man, in his efforts to peer into the unknown, has made use of this device from very early times. Not only has it been employed to locate water, valuable minerals and buried treasure, but also

in some instances to trace wrong-doers as well as to discover and diagnose disease in animals and human beings. In all its forms, it has been the "subject of much acrimonious discussion", as the "scientist has naturally shown an inclination to reject the reality of phenomena which he cannot explain on orthodox lines". It is noteworthy that the author considers he has at last discovered the physical causes of the movements of the rod, and concludes that they "are governed by the laws of electrodynamics as formulated by Ampère in 1820".

Apart from a general looseness of phraseology, the author puts forward what is perhaps the best case possible for the divining rod, and quotes a mass of apparently incontrovertible evidence of the reality of the water diviner's powers. It is, however, when he attempts a technical explanation of the behaviour of the divining rod, and a description of the methods employed, that his arguments become unconvincing.

As an up-to-date exposition of the application of the divining rod in all its forms to the location of water, and a description of the new methods recently introduced by the author, the book is both informative and interesting, but many of the statements and conclusions put forward lack conviction and will not be accepted by the physicist without further evidence.

Die experimentellen und theoretischen Grundlagen der Elektronenbeugung. Von H. Mark und R. Wierl. (*Fortschritte der Chemie, Physik und physikalischen Chemie*, herausgegeben von Prof. Dr. A. Eucken, Band 21, Heft 4.) Pp. iii + 126. (Berlin: Gebrüder Borntraeger, 1931.) 16 gold marks.

THIS monograph is, like others in the same series, an account of the subject which will be of use mainly to research workers in other branches of physics. After a short section on the theoretical basis of electron diffraction experiments, about eighty pages are devoted to the experiments themselves. Many of these will be familiar to readers of NATURE through references to them which have been made at various times in "Research Items" and elsewhere. The authors remind us, by their treatment of the subject, that the fundamental work in electron diffraction is now almost as well established as the methods of using X-rays; this, of course, is only natural, as much of the well-developed technique which had been acquired for X-rays was immediately applicable to the newer problems when they arose. Problems which could not be so treated, as, for example, diffraction by single atoms and by adsorbed films, presented little more difficulty, if any, owing to the present widespread knowledge of good vacuum technique.

There is a bibliography of papers up to April 1931, and the usual indexes. The book is, however, scarcely likely to come into the general use to which its merit would entitle it, as it is unjustifiably expensive for such a small production.

Physikalisches Handwörterbuch. Herausgegeben von Arnold Berliner und Karl Scheel. Zweite Auflage. Pp. vi + 1428. (Berlin: Julius Springer, 1932.) 99·60 gold marks.

IT is difficult to see how there can be a demand for a volume such as this, although it apparently exists, as we have here a second and enlarged edition. It falls between two extremes, and provides information which is too technical to be appreciated without a good knowledge of physics, and yet is not sufficiently detailed to be of much value to, say, an honours degree student. In the latter respect it differs markedly from its nearest equivalent in English, Glazebrook's "Dictionary of Applied Physics", which serves this purpose rather well. The list of contributors is, however, imposing, and promises an accuracy in their respective sections which is borne out by the perusal of a number of articles chosen at random. The articles are also, so far as can be judged in this way, reasonably up to date, and include such relatively new topics as wave-mechanics and Debye's theory of electrolytes. In one connexion it may have a quasi-permanent value—it may serve later on as a concise record of a good deal of the present state of knowledge in physics. The price of the book, although high, is not, one imagines, out of proportion to the labour involved in preparing it, and the binding and printing are, as is usual with Springer's books, all that could be desired.

The Automatic Stabilisation of Ships. By T. W. Chambers. Pp. x + 114 + 8 plates. (London: Chapman and Hall, Ltd., 1931.) 10*s.* 6*d.* net.

THE gyroscope has been applied to many purposes undreamt of by its distinguished inventor and were Foucault to visit the stabiliser-room of the Italian Atlantic liner *Conti di Savoia*, he would not know his own child, and would probably feel much as Faraday did when visiting a great chemical works. That ship of 45,000 tons is being fitted with three separate Sperry gyro-stabilisers, each of which has a wheel 110 tons in weight, which in order to keep the ship steady, will be revolved at 910 revolutions per minute. How the plant is constructed and fitted in the ship and how it is controlled and driven is fully explained in two articles in the *Engineer* for Jan. 8 and 15, 1932. Not long before, the same journal published a series of articles on the stabilisation of ships by means of water chambers and gyroscopes, and it is these articles which have been collected and published in this book.

Mr. Chambers deals clearly with both the theory of the gyroscope and the practical application of gyro-stabilisers and his book will, we believe, find its way into many shipbuilders' drawing offices. The subject is a fascinating one, and is but another example of a purely scientific invention which has been applied successfully to a practical engineering problem. E. C. S.

The Pioneer Work of the Systematist*

By The Right Hon. LORD ROTHSCHILD, F.R.S.

THE inquiry into the secrets of organic Nature may be divided into three categories of questions: (1) what organisms creative forces have produced on earth; (2) how they have produced them; and (3) what is the nature of the creative forces. It was at the time of Linnæus a comparatively simple achievement for one man to have enumerated all the animals then known, his "Systema Naturæ" of 1758 containing altogether fewer than 4300 species. That task is in our days a hundred times more difficult, not only on account of the vast number of species which have poured into collections, are still pouring in and will continue to do so for a long time, but also because research in systematics requires a much deeper knowledge of the morphology and bionomics of the animals classified. At the time of Linnæus and after, when systematics were in their infancy, individual specimens showing marked differences were as a rule diagnosed as representing distinct species, the unit called species being looked upon as essentially a constant.

Experience has now furnished a guiding principle in the facts that similarity does not necessarily mean relationship of the forms under observation, that dissimilarity is not necessarily evidence of specific distinctness, and that variability obtains in every species and every organ; and if these facts are kept in mind by the systematist, the reproach of superficiality often justly levelled at work in taxonomy can be borne with equanimity.

Variability is an essential character of everything alive. The concept of the constant species of former days is replaced by the concept of the flexible species, and the saying that like breeds like requires modifying into the statement that a population breeds a population with the same extent of variability. If like breeds like were being taken literally, we should have to alter it into like breeds unlike. For, strictly speaking, individuals are never alike whatever their relationship to each other. A calculation, for example, of the number of specimens required of the commonest British mouse-flea (*Ctenophthalmus agyrtes*) in order to find among them two absolutely alike in the number and position of the bristles on the body arrives at the amusing figure of many million billions, a figure certainly in excess of that of the whole flea-population of Great Britain, and tantamount to proving that there are no two specimens alike.

In studying the characteristics of each specific unit and drawing up diagnoses for purposes of recognition, the systematist renders service in two quite different spheres of work and thought. Being alone able to identify the species in the difficult group in which he specialises, he assists defensive biology in its task of safeguarding humanity against the ravages of health- or food-destroying organisms. Applied biology can only be a science if based on sound systematics. For example, when the Commission investigating bubonic plague in India had become definitely convinced that the plague was a rat disease transmitted to human beings through the agency of a particular species of rat-flea, no satisfactory explanation could be found why in Colombo and the city of Madras an outbreak of plague did not last long, although rats and rat-fleas abounded. The puzzle was solved when Dr. Hirst took the matter up and sent to my brother the flea material collected in the towns mentioned during a period when there was no plague and again when an outbreak occurred. The examination of the material proved that the flea ordinarily infesting rats at Colombo and at Madras was not (as the Commission had assumed) the plague-flea *Xenopsylla cheopis*, but *X. astia*, a very similar, but different species, which, by experiments, Dr. Hirst proved to be an inefficient carrier of the disease. When during the campaign in Mesopotamia camps became infested with rats, the British Museum could give the reassuring answer to an inquiry that there was no danger of a serious outbreak of plague, because the rat-fleas collected were *X. astia*, none belonging to *X. cheopis*.

The help which the systematist can extend to applied biology, however, is for him only a side-issue or a by-product; he is a student of pure science, devoting his time to the discovery of new species, of new connexions between them and of new facts bearing on the relation between the species and its surroundings, the driving force in this pursuit of knowledge being the irresistible attraction which the subject has for him.

The describing of new species and finding the right place for them in a given scheme of classification and the identifying of species may seem work of an elementary kind, necessary and useful, but nevertheless rather superficial. If systematics ended there, they might satisfy the collector perhaps, but scarcely the scientific mind. But this preliminary work is only a part of systematics. A natural classification is based on blood-relationship, and therefore entails an inquiry into the evolution of the species classified. Systematics change from a static study of form into a dynamic study of evolution. A species is like a book, which must be read critically and in its entirety. Unfortunately the systematist is much handicapped, as in the case of mammals, birds, insects and some other classes he has to be content with the portions of the animal which it is customary to preserve in collections. But even so, the contemplation of the skins and skulls of mammals, of the skins of birds, and of the dried insects reveals to him the

* From the presidential address to Section D (Zoology) of the British Association delivered at York on Sept. 1.

latitude and the kind of variability and variation in the species of which he has adequate material, and enables him to compare results with the biologists who have studied the flexibility of species with the view of ascertaining whether the variability is purely fortuitous or whether there is system in the apparent confusion, many so-called laws of development having been discovered in the course of such inquiries.

Now, according to the experience of the systematist, such laws are rules with exceptions, sometimes the normal and the exceptional balancing each other, and it may be stated in general that the opposite must always be expected to occur. Exceptions have a certain fascination, not only for the writers of novels and plays, which are mostly based on exceptional characters or exceptional situations, but also for the biologist. As exceptions are comparatively rare, it requires large collections or long observation to discover them, and if there is no known exception to a certain rule of development, one has the feeling that it will some day be discovered. Take as an example the gallinaceous birds; among these game-birds are found the most striking instances of sexual dimorphism, the cocks exhibiting an often marvellous display of colours, as in the peacock, pheasants, fowls and others, the females being comparatively inconspicuous. It is therefore somewhat startling to find just in this order a genus in which the colours and behaviour of the sexes are reversed. In most species of the Oriental genus *Turnix*, a kind of quail, the females are larger than the males, bear a much brighter plumage, utter the call-note, fight each other for the possession of a male, and leave it to the male to incubate the eggs and to take care of the young.

Of the two classes of animals which I have studied more particularly, birds and Lepidoptera, the coloration is on the whole more constant in birds within the species at the same locality, apart from differences of sex and age, than in butterflies and moths, and individual di- and polymorphism is decidedly more common in the insects than in birds, but it is by no means absent among the latter. Dark and light phases long known to occur regularly among certain raptorial birds, for example, harriers, have during recent years been discovered to exist also here and there in other groups of birds, where they have formerly generally been described as distinct species. Such a correction had also to be made in the systematics of the American genus *Rhamphocœlus*, where red and yellow forms differing only in colour are now regarded as being individuals of one species, intermediate examples of an orange colour also being known, as well as very exceptional examples, such as the aberration *Rhamphocœlus dunstalli* Rothsch., in which the red and yellow colours extend to parts of the body other than those normally so coloured. The gaily coloured parrots furnish other examples of dichromotism; for example, the parakeet, *Eos fuscata* Blyth, which is a fairly common bird in New Guinea, appears in a red and a yellow form in the same place, both forms being about equally frequent, the red one slightly preponderating, and the lory *Charmosyna stellæ* Meyer, which appears in a black as well as a red form.

Besides colour and pattern, the size and shape of the specimens and their appendages and the structure of the secondary sexual characteristics of many kinds are found to be of great help in species classification, but experience has shown that none can be relied on unreservedly any more than colour or pattern. The comparison of the frequently exaggerated distinctions of the males, such as the horns of stags and beetles, the long forelegs of beetles, the stalked eyes of certain flies, etc., has led to the discovery that the size of these organs is not always proportionate to the size of the body, but that the ratio in the development of such appendages increases disproportionately with the size of the specimens; in a small male of a species of Longicorn beetle the antenna may be a little longer than the body, while in a large specimen of the same species it may be several times longer than the body. Collections bear out this law of growth almost completely, but only almost. The stag-beetles are one of the families that have early directed attention to the remarkable development of their mandibles, which are sometimes so large, and the point of gravity therefore placed so far forward that the specimen has to assume a semi-erect position in order to keep its balance.

Such exceptions from general rules are of great interest, and it is therefore the duty of the systematist who comes across an exception—generally accidentally—fully to record it. Does it not seem evident from the cases mentioned that Nature can break a rule of development, just as Nature has created species and destroyed them? After all, the law is only our deduction based on the organisms we find provided by working methods of Nature we endeavour to discover. Circumstances may arise which interfere with the usual 'routine' of growth. The rule of growth illustrated by the stag-beetles, and corroborated by breeding of plants and animals, leaves no doubt that the characteristics in size and weight of an individual are not inherited and therefore are of no importance in the evolution of species. The test can be made in collections by comparing the closely related species of a genus with each other.

It must be clearly understood that in speaking of the unimportance for evolution of the bulk of individuals and the size of certain appendages, we referred to specimens of the same country, that is, individuals belonging to the same interbreeding population. In comparing the populations of two different countries the question assumes quite another aspect. In the systematics of birds the study of subspecies or geographical races has developed into a fine art. Size and shades of colour furnish the main distinctions between subspecies, and here we observe this important contrast that, while the difference of, say, 6 mm. in the wing-lengths of specimens from the same country is of

no importance, because not inheritable, the difference of 2 mm. between the populations of two countries is an inheritable quantity and therefore qualifies the two populations as being subspecifically distinct from one another. The evolution of the subspecific size-difference evidently starts with a shifting of the *average* size.

In our researches on the swallowtail butterflies we came across a combination of distinctions which is most instructive in an inquiry how the subspecies have come into existence. In a large number of species of butterflies and moths the geographical forms are separated by differences in the structure of the organs of reproduction and in colour and pattern. The important point is this, that the two sets of differences vary independently of each other within each subspecies.

The individual characters of the ancestral specimens do not influence the formation of the new race, only what is inheritable is of importance, and what is non-pathological and therefore adaptable to new and possibly less congenial surroundings.

Systematics and morphology are different expressions for the same kind of research, and I have no doubt that experimental biology will likewise have such a deepening influence on systematics that the superficial gap existing between the two lines of research will disappear too. Knowledge *begins* with the observation of phenomena, not with the experiment. The areas inhabited by the geographical forms of the species we have studied are either strictly separated, as in the case of island forms, or they are contiguous, there being between the areas no gap uninhabitable for the species, such as water would be for a dryland species, or a desert or savannah for a woodland species; or the areas may overlap. What happens when the areas touch or overlap and the geographical forms come in contact with one another? In a critical survey of the birds of Kenya Colony, lately published by Dr. van Someren in the Tring Museum periodical,[1] every now and again the author records the observation that perfectly distinguishable subspecies intergrade in the intermediate district, where the two evidently have interbred and produced an impure population, not strictly distinguishable from, or identical with, either present subspecies. The phenomenon occurs very frequently, as must be expected; for the breaking-up of a species into geographical units cannot at once result in sexual aloofness. This, however, is a point which should be further investigated.

Not all geographical races amalgamate when they come together. Many of them have become so different that they can live side by side, each being an independent community not interbreeding with the other. Sometimes we find both amalgamation and specific distinctness among the forms divided from a parent stock, as is the case in the sister species cat-flea and dog-flea. The home of the genus *Ctenocephalides* to which both belong is Africa. Tropical and South Africa are inhabited by a subspecies with short head, and the Nile countries by one with a long head, the two intergrading in the Sudan and Uganda. From India to the Papuan countries, with the exclusion of Australia, a third race occurs, and in Europe and Central and North Asia the cat-fleas were represented by the flea occurring on dogs and wolves. When the Egyptian house-cat came to Europe, it brought with it the long-headed form of *Ctenocephalides felis* Bouché, which thereby came into contact with the palæarctic shortheaded dog-flea. One might have expected that they would hybridise and amalgamate, but they did not. The morphological differences are but slight, but a physiological barrier had arisen which kept and keep the cat- and dog-fleas as species, although they may occur together on the same individual of the host.

Systematics are not concerned with the study of species and their variations only. The species have to be grouped into genera and then into higher categories, all according to relationship, that is, according to descent. As in the study of subspecies the systematist must enter upon geography, so in the search for the past connexions between genera and families his research becomes linked with the past history of the earth and sometimes throws light on this history. If he can prove that two genera now widely separated geographically are really of common stock, then there must have been a means of communication in former times which is now absent. If I may draw again on my brother's studies for an illustration, we will take the distribution of the queerest-looking fleas as yet discovered, the Australian *Stephanocircus* and the American *Craneopsylla*, in which the anterior portion of the head is divided off as a laterally compressed helmet. They are closely related, and the group originated in South America, where occur several allied genera and a genus connecting the group with more normally built fleas. They are only found in the Andesian countries from Patagonia to Ecuador (possibly occurring farther north), and in a modified form as *Stephanocircus* in Australia, nowhere else. The assumption that there was at one time a bridge between South America and Australia is the only explanation at all satisfactory. This conclusion is supported by another genus (or group of genera), *Parapsyllus*, which is plentifully represented by species in the same Andesian countries (not in eastern Brazil, the Amazons and Guianas), and recurs in one species on the islands in the South Polar Sea and in southern districts of Australia. The distribution of both genera evidently took place from west to east.

Although the systematist is primarily concerned with the organisms as produced by Nature, and not with the creative forces which have evolved them, his researches extend to so many different species that he is bound to collect evidence bearing on those forces and their working. There are, in fact, many questions which can only be answered with the help of extensive systematic collections.

A New Indian Academy of Sciences

IN the fog of political turmoil in which India has for so long been enshrouded, the remarkable scientific developments which have taken place in recent years have been somewhat overlooked. To those acquainted with the conditions prevailing at the beginning of the century, when scientific research was confined almost solely to the specialist Government departments, such as the Survey of India or the Geological Survey, and to the two veterans, who are still happily with us, Sir J. C. Bose and Sir P. C. Rây, the present conditions must appear remarkable.

The scientific renaissance of India dates from the reorganisation of the universities about twenty years ago following on the report of the Curzon Commission. Prior to this the university colleges were little more than high schools, and even so late as 1910 it was possible to take a degree in physics without undergoing any laboratory instruction. With the introduction of honours courses and the consequential increase of staff, the value of scientific research was gradually recognised, so that at the present time the output of original work from the Indian universities compares not unfavourably with that of the West. An outcome of this development has been the formation of new specialist societies which may all be regarded as the offspring of the Indian analogue of the Royal Society, the Asiatic Society of Bengal, which celebrated its centenary in 1913. This old society, full of vitality as it still is, has the disadvantage that its influence is confined practically to Calcutta and its environs. In 1914 the Indian Science Congress was founded, a peripatetic body modelled on the lines of the British Association. This body met with immediate success as is testified by the large attendance at its meetings and the large number of scientific communications read before it. The Indian Science Congress does not, however, undertake the publication of these communications except in abstract, and a natural nationalist spirit, coupled with the long delay associated with publication in European and American journals, has resulted in the foundation of the Indian Chemical Society and of the *Indian Journal of Physics*.

The most recent development is the formation of the Academy of Sciences of the United Provinces, with its seat at Allahabad. A movement for the creation of an Academy was started by Prof. M. N. Saha in 1929, and advantage was taken of the meeting of the Indian Science Congress in 1930 in Allahabad to discuss the functions of the proposed Academy. As a result of the interest and sympathy shown it was registered in December of that year. The first volume of its *Bulletin* has now been published, and this contains an account of the inaugural meeting held on March 1. The main objects of the Academy, of which Prof. Saha is the first president, are the encouragement of science in its various branches, more especially in the United Provinces, and the publication of the results of scientific research, either in its *Bulletin* or in the form of *Transactions* and *Memoirs*. The membership of the Academy, as in the case of the Asiatic Society of Bengal, is divided into two classes, fellows elected for their scientific eminence, the number being limited to thirty, and ordinary members of whom no special qualifications are required. The successful inauguration of this body is welcome evidence of the increasing value now attached to scientific research in India, but it seems somewhat questionable if the publication of a new journal is desirable.

The first *Bulletin* contains twenty-seven original memoirs and it is divided into the following heads :—mathematics, physics, chemistry, industrial chemistry, zoology, botany and general. Under the last heading there is an interesting paper by Sir C. V. Raman on "Spin of Light". Many of the communications could with equal advantage have appeared in the *Indian Journal of Physics* or in the *Journal of the Indian Chemical Society*, and it seems likely that some of them will be published *in extenso* elsewhere, since they are only short abstracts and are so headed. Time will show if there is a real need for the *Bulletin*, but with so distinguished and energetic a president and with such admirable secretaries as Prof. P. S. MacMahon and Prof. A. C. Banerji, the future success of the Academy seems assured, and there is little doubt that it will do much to stimulate the research spirit in the Universities of Allahabad, Lucknow, Aligarh and Benares.

The Colloid Aspects of Textile Materials

EIGHT years ago, the Faraday Society made an interesting experiment in devoting one of its discussions to "Physical and Physico-Chemical Problems Relating to Textile Fibres". At that time the study of fibres was in its infancy, with an uncertain future, and all workers in the subject owe the Society a debt of gratitude for early encouragement during difficult years. Courageous patronage deserves a rich reward, and this the Society achieved in the outstanding success of the second discussion on "The Colloid Aspects of Textile Materials", which was held in the Chemistry Department of the University of Manchester on Sept. 21–23. The meeting was noteworthy for the number and distinction of its overseas visitors and contributors, among whom were included E. H. Büchner (Amsterdam), E. Elöd (Karlsruhe), R. O. Herzog (Berlin), G. van Iterson (Delft), J. R. Katz (Amsterdam), P. Krais (Dresden), H. Mark (Ludwigshafen), M. Mathieu (Paris),

O. Roehrich (Paris), S. E. Sheppard (Rochester, N.Y.), H. de Witt Smith (New York), H. Staudinger (Freiburg), and J. J. Trillat (Paris).

During the years which have intervened between the two discussions, textile fibres and related substances have been studied by a wide variety of methods, and whereas in 1924 the properties of fibres could be explained only in terms of mechanical analogies, a much closer molecular interpretation of fibre structure has now become possible. It is generally recognised that fibres are constructed from long-chain molecules in which a definite unit is regularly repeated. In the case of cellulose fibres, the macromolecule consists of a chain of glucopyranose units linked through positions 1 and 4, while the corresponding units in the case of protein fibres are -CO-CHR-NH- groups, the constituent α-amino acids being linked in this way to form a long peptide chain possessing side chains which vary in character according to the nature of the protein.

The real existence of such long-chain molecules has, in the case of cellulose, been demonstrated by Haworth using an ingenious application of the methylation technique. If the long molecules are not looped, hydrolysis of methylated cellulose must yield, in addition to trimethyl glucose, a small amount of tetramethyl glucose from the terminal glucose units. The relative proportions of the two compounds gives a measure of the length of the chain and its molecular weight. In the case of cotton cellulose the mean molecular weight was found to lie between 15,000 and 30,000. It is satisfactory to note that Stamm, using Svedberg's ultracentrifugal technique, obtained a value of 40,000, but Haworth's determination acquires exceptional significance because the molecular weight can be referred definitely to a single cellulose chain. By means of the ultracentrifuge, Svedberg has also determined the molecular weight of the monodisperse, soluble proteins and obtained values which were 1, 2, 3 or 6 times 34,500. Similarly, in the case of derivatives such as cellulose acetate, the beautiful technique used by Büchner in measuring osmotic pressure has given values of the order of 35,000 for the mean molecular weight. Herzog pointed out, however, that the cellulose acetate used was probably not homogeneous and in a case which he had examined, the crude product gave fractions varying in molecular weight from 20,000 to 140,000.

The point is important because Staudinger, from viscosity measurements with cellulose solutions, concluded that the molecular weight of cellulose was of the order of 120,000. The validity of his viscosity law for compounds of high molecular weight was the subject of detailed discussion, a point of difficulty being the insistence that the molecules must be regarded as long rigid rods. Evidence for their flexibility was adduced by Adam from the properties of monomolecular films of long-chain compounds on a water surface, and it was further indicated by Sidgwick and Rideal that flexibility of the chains need not invalidate the viscosity law. While some difference of opinion still exists as to the precise magnitude of the molecular weight of the long-chain molecules of animal and vegetable fibres, it is satisfactory that all methods agree in giving a molecular weight of the order of 30,000. That such widely different substances as cellulose and the proteins should have molecular weights of the same order of magnitude seems to suggest the existence of a common determining mechanism.

As regards the structure of the fibres composed of such molecules of high molecular weight, there has been a certain difference of opinion. On one hand, Mark has suggested that the molecules are arranged in bundles to form discrete micelles which are the secondary units of fibre construction. Neale and others see no necessity to postulate anything other than long-chain molecules which crystallise with varying degrees of perfection in the same fibre. Actually, there appears to be no essential difference between the two views, and a possible mode of reconciliation is to be found, as Astbury indicated, in Zwicky's recognition of a mosaic or secondary structure in the more familiar crystals. In the case of animal fibres at least, the real existence of micelles, less permeable to water than the fibre as a whole, has been abundantly demonstrated by swelling experiments which have been developed to give a measure of micellar thickness in good agreement with that derived from X-ray and other evidence. With reagents other than water, the micelle structure may be dispersed, as in the case of wool fibres in acid solution, but removal of acid results in its reappearance.

The swelling of fibres, as suggested by Katz, may therefore be intramicellar, intermicellar or permutoid. In the case of wool, rigidity experiments and X-ray studies have clearly indicated that swelling occurs both by intra- and intermicellar water adsorption, and it was argued from the hysteresis phenomena in Marsh's determinations of the influence of adsorbed water on the electrical conductivity of wool, that intra- and inter-micellar water must function very differently in conductivity measurements. A possible method of discriminating between the two was suggested, based on the fact that the first five per cent of water adsorbed by wool is intramicellar. Similar considerations apply to cellulose, and Miles and Mathieu agree in concluding that nitration of cellulose does not proceed on an impervious micelle, but that it is penetrated by acid and nitrates throughout its whole structure simultaneously.

As regards the existence of micelles in solutions of cellulose and its derivatives, Adam showed that the ethers spread completely on water and if micelles exist in the original solution, cohesion is insufficient to prevent the formation of a monomolecular film. The esters and nitrates, on the other hand, showed incomplete spreading, while cellulose in cuprammonium solution was precipi-

tated and not spread on water. Thus no decision can yet be made as to whether or not the micelles of cellulose retain their existence in solution.

Cohesion within the micelles of the wool fibre was shown to depend partially on salt formation between the acid and basic side linkages of the long chain molecules, as well as cystine linkages which are far more resistant to chemical attack. By analogy with the proteins, Mark was led to hint that the subtle differences between native and treated cellulose might depend on similar cross-linkages between the long-chain molecules of native cellulose, such linkages being opened by subsequent treatment. His hypothesis must be regarded as an extension of the views of Neale, who discriminated between two methods of modifying the properties of cellulose—by reactions which alter the reactivity of the hydroxyl groups associated with the long molecules, and those which modify the properties of cellulose by fission of the glucose chains.

In the case of wool and related fibres, the side linkages which have been identified as salts of arginine and glutamic acid, play an important part in determining the configuration of the long peptide chains. These have been shown by Astbury to be coiled into a series of pseudo-hexagons, whereas the peptide chains of silk are normally in the extended form. Since the side chains of silk are mainly non-reactive, it is reasonable to refer the coiled character of the peptide chains in wool to the endeavour of the more reactive acid and basic side chains to realise a condition of minimum potential energy by salt formation. Actually, a regular transition exists from silk with non-reactive side chains, through wool with salt-forming linkages, to feather which, according to Astbury, consists of long peptide chains bridged across by true peptide linkages. The importance of such side chains in determining the physical and chemical properties of proteins has now been fully recognised. For example, Miss Lloyd emphasised the part played by their length and reactivity in determining the extent of protein hydration and swelling. Similarly the salt linkages of wool are of fundamental importance in dyeing processes, and if Elöd's exhaustive application of the Donnan theory of membrane equilibria to the dyeing of wool with acid dyes is combined with the recognition of salt linkages, a precise interpretation of the mechanism of dyeing is possible. There can therefore be no doubt that the ingenious technique developed by Hughes for the study of protein films on water will prove invaluable as a simple and direct method of determining the properties of the fundamental long-chain protein molecule and its associated side chains.

J. B. SPEAKMAN.

News and Views

The Wren Tercentenary Celebrations

SIR CHRISTOPHER WREN was born at East Knoyle, Wiltshire, on Oct. 20, 1632; and to mark the three hundredth anniversary of his birth a special service will be held in St. Paul's Cathedral on Oct. 20 at 4 P.M., and will be attended by the Lord Mayor and Sheriffs in state, and by representatives of the Royal Society, the Royal Academy, the Royal Institute of British Architects, the London Society, the Wren Society and other bodies. The service will be broadcast. The Dean and Chapter are also arranging an exhibition of portraits, models, documents, relics, etc., in the Trophy Room in the Cathedral which will be opened by Sir F. G. Hopkins on Oct. 10, and will be open to the public from Oct. 16 until Nov. 12 at 11 A.M. to 4 P.M. Though it was the rebuilding of the City of London after the Great Fire of 1666, which gave Wren a unique opportunity of displaying his genius as an architect, he had even before then designed the Pembroke College Chapel, Cambridge, and the Sheldonian Theatre, Oxford. His plans for rebuilding the City of London with a series of streets crossing each other at right angles, it is true were not adopted, but he was responsible not only for the design of St. Paul's Cathedral but also for the plans of some fifty churches, besides the Royal Exchange, the Custom House, Chelsea Hospital, Hampton Court, Greenwich Observatory and Buckingham Palace. The first stone of St. Paul's was laid on June 21, 1675, and the last stone set in 1710, thirteen years before Wren's death, which occurred on Feb. 25, 1723.

Wren's long life covered a part of the reign of Charles I, the period of the Commonwealth, the reigns of Charles II, James II, William and Mary, Anne, and the first nine years of the reign of George I. With the great social and political movements of the time he had little to do, but he will always be remembered as a distinguished man of science and England's greatest architect. From the days he was taught by Busby at Westminster School and came under the influence of Wilkins at Wadham College, Oxford, he gave evidence that he possessed unusual powers of mind, and at Oxford he quickly took a place among the devotees of science through whose efforts the Royal Society was founded. Like most of his contemporaries he made experiments in many branches of physics, and was particularly noted for his mechanical skill. At the age of twenty-five years he was appointed to succeed Rooke in the chair of astronomy at Gresham College, London, and four years later he succeeded Seth Ward as Savilian professor of astronomy at Oxford. This post he still held when he began his great career as an architect. The Royal Society was indebted to him in many ways. It was he who drew up the preamble to the charter of incorporation granted by Charles II in 1662; in an address in 1664 he urged the members not to flag in their efforts for it should be the aim of the Society to "plant Crabstocks for posterity to graft on", and when deeply engrossed with plans for a dozen churches he yet found time to serve as president. Many tributes to his genius

have been paid, and here it may be recalled that Newton placed him beside Wallis and Huygens as one of the leading geometers of the age.

Sir Philip Magnus, Bt.

THE many friends of that veteran educationist, Sir Philip Magnus, Bt., will be interested to learn that on Oct. 7 he celebrated the ninetieth anniversary of his birth. Sir Philip attended University College School, London (possibly he is now the oldest of its scholars), graduating afterwards at the University of London. He was secretary of the City and Guilds of London Institute from 1880 until 1888, and within this period was a member of the Royal Commission on Technical Instruction. Afterwards, for some thirty years, he was superintendent of the Department of Technology, City and Guilds of London Institute. Long devoted to the interests of the Royal Society of Arts, Sir Philip was elected its chairman of council in November 1927, succeeding Sir Thomas Holland. An inaugural and most comprehensive address delivered in that capacity was entitled, "The Royal Society of Arts: its Services to Trade and Training".

Prof. H. L. Le Chatelier

CONGRATULATIONS are also extended to Prof. Henry Louis Le Chatelier, the distinguished French chemist, who this week (Oct. 8) celebrates his eighty-second birthday. Elected a foreign member of the Royal Society in 1913, the distinction of the Davy Medal was conferred on him in 1916. As the result of prolonged investigation, he introduced the Le Chatelier thermoelectric couple, and inaugurated a new period in the measurement of high temperatures. One of the pioneers of micrometallurgy, he was among the first to provide exact methods in the science of industrial silicates. His scientific work has always been closely related to practical applications. Prof. Le Chatelier is the author of many memoirs and papers in scientific journals.

The Gregorian Reformation of the Calendar

THIS week is the 350th anniversary of the reform of the calendar ordained by Pope Gregory. The day following Oct. 4, 1582, was called Oct. 15. It is not always remembered that, in addition to the calendar changes, greatly improved lunar tables were introduced for the purpose of computing the date of Easter. An article in the *Southwark Record* notes that the necessary calculations were executed by Luigi Giglio (Aloysius Lilius), Ignatius Danti, and Christopher Clavius. It also points out that the ten days stolen from October are now being slowly repaid, as the 'Summer Time' reckoning gives October an additional hour each year.

Lighting of Picture Galleries

MANY visitors to picture galleries must have noticed that pictures are often hung on the walls of most galleries in such a way as largely to defeat the very object for which these expensive institutions exist. It is about 120 years since Prof. Henry in America first directed attention to the need for collaboration between architects and men of science in planning buildings suitable for music and speech. Gradually the inertia of professional conservatism in this matter has been partially overcome; there remain, however, important optical problems relating to the lighting of rooms in which pictures are to be displayed. Here the physicist can help, and already authorities in London are making experiments. At the Tate gallery, for example, may be seen the advantage of hanging pictures on only one wall of a room, and various schemes of artificial lighting are being tried at the National Gallery itself. It is now generally agreed that pictures in London should be glazed if only to keep them clean and free from deleterious gases. But there are other reasons too; experience has shown that enthusiasts cannot refrain sometimes from touching a canvas, and that pins or other things projecting from the headdress of lady visitors to a gallery have been known to scratch the pictures and do incalculable damage. Since it is the practice to hang all pictures flat against the walls, the reflection of those on the opposite wall, as well as that of an observer, frequently renders it very difficult to make out detail in a painting. For example, in Room 25 of the National Gallery, Trafalgar Square, the large equestrian portrait of Charles I reflects well all the other pictures in that room, a good deal of the roof and the large and extremely ugly warming device and seat in front of it.

Reflection from Glazed Pictures

IN directing attention to the question of avoiding reflection from glazed pictures, Mr. Robert Howden has rendered a useful service both to artists and the public. His paper, read before the Royal Society of Arts on Oct. 3, clearly stated the elements and difficulties of the problem, and it is significant that Sir Edwin Lutyens was in the chair. Mr. Howden recommends replacing the usual flat glass by a sheet bent into a parabola. The adaptation of this device to shop fronts has recently been developed by Mr. G. Brown, and the effectiveness of such a scheme may be seen by viewing the interior of a motor show-room at 88 Regent Street, London, through the curved plate glass windows. No reflection of the street can be seen and only the contents of the show-room is visible from without, so that the window itself does not seem to exist. If this could be applied to pictures in public galleries, it would indeed be a boon. But there is the question of cost and the ever-haunting thought that perhaps some other and simpler solution of the problem may not be out of reach. In order to be effective, pictures hung high up would require a different curvature of glass from those on a level with the eye, and then all the varieties of sizes and shapes of canvases or panels would offer further difficulties. Would it not be as well to try first the simple device of tilting the pictures a little forward? Why is that not done in the public galleries? We think this would at least be an improvement on existing conditions and, if sufficiently successful under the usual system of lighting, the walls of new galleries could be built so as to lean a little

inwards. It might be worth while to construct a light wooden framing that would cover one of the smaller walls of the National Gallery, to hang upon it pictures with dark backgrounds and then to tilt the screen forwards and note the improvement in visibility under the conditions of top lighting in use there.

Museum Improvements

Two articles of real value to museum curators appear in the *Museums Journal* for September. The first, by Dr. L. J. Spencer, discusses the artificial lighting of museum cases, and recommends the use of strip lights along the upper portion of the case, and the painting out of shadows cast by solid shelves. The assumption in such a case is that ordinary daylight lighting is ignored. Diagrams illustrate some of the cases of minerals in the British Museum lit by the method described, one tall (10 ft.) case showing a specially neat method of making use of the otherwise useless upper portion, by the fitting of transparent pictures illuminated from behind. In a second article, Mrs. Joan C. Stevens suggests a way of replacing the very expensive jointed figures used (where they can be afforded) for the display of costumes. With a little ingenuity effective figures can be made at a small cost, with cylinders of rabbit netting. The cylinders, head, arms, body, etc., can be 'bent' into shape as desired, and in proper position can be supported by strengthening struts of wire or wood. If the illustrations represent the results of this process, the home-made figures should find a comfortable home in many a museum, impoverished or otherwise.

British Commercial Gas Association

THE British Commercial Gas Association, founded for co-operative publicity effort in the gas industry, held its coming-of-age meeting in Leeds during the past week. Prince George, after seeing something of the manufacture of gas and gas appliances in the city, attended the dinner on Tuesday evening and gave an interesting review of the achievements of the industry. Major Geoffrey Kitson, in his presidential address, set forth further particulars of the present conditions, stating among other things that there are now five million 'slot consumers' on the books of the industry; that £180,000,000 of money and a yearly consumption of 18,000,000 tons of coal, are involved; and that 100,000 workmen are employed. He alluded to the advances being made in new directions, and in the afternoon, Mr. A. W. Smith, general manager and secretary of the Birmingham Gas Department, stated in his paper that authority has been obtained from the Home Office to run a test vehicle on the road with special steel cylinders containing gas at a pressure of 3000 lb. a square inch. It is hoped that gas so supplied may also be used for country houses and farms in districts remote from gas mains.

The executive chairman, Sir Francis Goodenough, at the opening of the Conference, spoke of the difficult days sure to follow upon the completion of the electricity grid, controlled by the Central Electricity Board. He foresees a desperate effort to get business for the grid "backed up more and more from Whitehall". It was in the gas industry that Sir Francis gained his first laurels as an authority on salesmanship and he insisted on the importance of perfecting the commercial side and of practising individual as well as collective enterprise. Major Kitson, who is chairman of the Leeds City Gas Department, urged the importance of gas and electricity, by co-partnership and concentration, setting themselves at once to achieve a national ideal of service in the most economical extraction of the potential heat, light and power from the great reservoir of energy—our sole native source—the coal fields. If the spirit and demeanour exhibited by Major Kitson prevailed more generally it would be a matter for congratulation. Extravagant *ex parte* statements by the advocates of the two agencies where their services overlap are greatly to be deplored, and they appear to be increasing. Among other things it is to be remembered that the exact measurement of the efficiency of heating appliances is still a subject of difficult scientific investigation. It is appropriate to say that in this and other technical problems, the University in the city where the Conference was held has long co-operated in a fruitful way with the Institution of Gas Engineers and that it has a chair of coal gas and fuel industries founded as a memorial to a great gas engineer, the late Sir George Livesey. In this and one or two other university centres in Great Britain, the scientific education of the gas engineer is now seriously taken in hand and is producing a long-needed type of recruit.

International Scientific Investigation of Population Problems

THE first World Population Conference was held under the auspices of the International Union at Geneva in 1928 and the second Conference at London in 1931. The proceedings of these Conferences have been published. In addition, three standing committees organise and to some extent subsidise research (The International Union for the Scientific Investigation of Population Problems: its Foundation, Work, Statutes and Regulations. Pp. 28. London: c/o Royal Geographical Society, 1932). It might perhaps be a matter for debate whether the results so far published justify a new and cumbrous organisation. But it is another matter when we take into account the value of an attempt to look at population problems from an international angle. All population problems have two aspects—a domestic and an international. The problem of emigration is a case in point. It may be that too much importance has been sometimes attributed to population movements, when, for example, war has been traced to over-population. But there can be no doubt that in many subtle ways population movements do affect international relations very profoundly. Thus if the Union can keep international aspects to the front, it will be justified whatever may be the value of the research which it directly advances. It may perhaps be said that in the long run the successful

ordering of world affairs will depend upon the international handling of such matters as emigration and others with which the Union deals, and it may be hoped that the Union will prosper under the chairmanship of Sir Charles Close, who has succeeded Dr. Raymond Pearl in that office.

Greek Earthquake of Sept. 27-28

DURING the night of Sept. 27-28, a severe earthquake occurred in the Chalcidice district of Greece. Seven villages were entirely destroyed, more than 3000 houses were ruined, and 141 persons were killed and 403 wounded. In Salonica, several of the public buildings were damaged. From the brief accounts so far received, the epicentre seems to lie between Salonica and Mount Athos. Montessus, in his "Géographie Séismologique" (p. 253), defines three seismic zones in this part of Greece, near the towns of Salonica, Izvoro and Kavala, respectively, the recent earthquake being probably connected with the second of these zones. The shocks were strongly felt in Bulgaria, in the Strumitza valley, in or near which the great earthquakes of April 14 and 18, 1928, occurred, but the epicentres of these earthquakes lay about eighty miles to the north of the area recently disturbed.

West Indian Hurricane Season of 1932

THE West Indian hurricane season of the present year will rank as one of the notable ones, since two storms of the first magnitude have already been reported. The particulars of the more recent of these that have appeared in the *Times* of Sept. 28 indicate a phenomenon of an intensity very much above the average, the speed of the wind being said to have reached 120 miles an hour at times in Puerto Rico on Sept. 27, where at least two hundred people have been killed. The storm is said to have been even more destructive there even than that of Sept. 13, 1928, and to have been the worst in the island's history. An official figure for the maximum speed of the wind will unfortunately not be available owing to the fact that the anemometer on the roof of the Weather Bureau at San Juan was destroyed with the tower on which it was mounted. The particulars given of the track do not indicate anything very abnormal. Many September storms pass to the south of San Domingo, as did the recent storm; they generally move towards west-north-west. In this case, however, the centre passed near the Virgin Islands and was on Sept. 28 apparently moving directly towards Jamaica, which suggests a nearly due westward motion. Such tracks are more common in August than in September and have generally passed close to the north coast of Yucatan to Mexico, without having begun the 'recurve' to a north-eastward movement characteristic of northern tropical hurricanes, which carries so many West Indian storms into the Gulf States.

Cloudburst near Bakersfield, California

A CLOUDBURST is reported to have occurred late in the night of Oct. 1 near Bakersfield, California, and to have caused water to advance like a tidal wave 40 feet high down a narrow cañon, sweeping away fifteen bridges, destroying railways and overturning locomotives, with considerable loss of life. Bakersfield lies within the American counterpart of the northern Sahara and the subtropical deserts of Arabia and Persia. The disaster must have occurred within or very near to an area with a mean annual rainfall of less than ten inches, which makes it appear at first sight the more remarkable. Cloudbursts are, however, regarded by meteorologists as nothing more than extreme examples of 'instability rainfall' of the thunderstorm type—they are in fact often accompanied by thunder—and their incidence in normally dry regions has therefore nothing very anomalous about it. The disastrous floods at Louth (Lincolnshire) on May 29, 1920, due to an exceptionally severe thunderstorm combined with an unfortunate accidental blockage of the narrow valley down which the water might otherwise have passed with little damage, occurred in one of the driest parts of the British Isles. The extent of the damage is often governed by such accidental circumstances, and it is interesting to note that a fall of rain at Cranwell (Lincolnshire) on July 11 of this year almost exactly equalled the heaviest fall measured in and around Louth on May 29, 1920, and came in a shorter time, without disaster.

Climatic Changes in Central Asia

THE theory that Central Asia, particularly the Tarim basin, furnishes evidence of progressive desiccation during historic times is refuted by Lieut.-Col. R. C. F. Schomberg in a paper on alleged changes of climate in Southern Turkestan in the *Geographical Journal* for August. Lop Nor, he maintains, is not drying up. Its change of level is due to the loss of the Qurug River water. That river changed its course and though its waters reach the lake they do so by a longer course via the Tarim River and so presumably are partly lost on the way. The Qurug is said now to have returned to its old course. Col. Schomberg gives reasons for denying that any of the rivers are drying except where increased cultivation calls for more irrigation water. He lays no value by the so-called evidence of depopulation in a land where the population is always sporadic and insecure. Dust storms, moving sand, and insect pests may easily cause abandonment of peopled sites. He denies that the many dead *toghraqs* or desert poplars necessarily imply want of water. Sometimes they are killed by the rapidly growing tamarisk, sometimes by disease and sometimes even by too much water. The paper is full of valuable arguments bearing on this much-debated problem.

New Antarctic Lands

AFTER about a century's neglect the Enderby Land area of Antarctica was revisited in the summer of 1929-30 by Sir Douglas Mawson in the *Discovery*, of the British, Australian and New Zealand Antarctic Research Expedition, known for convenience as B.A.N.Z.A.R.E. The *Discovery* continued her work

in 1930–31. A map of the numerous discoveries accompanies a paper by Sir Douglas Mawson in the *Geographical Journal* for August. Mawson's map extends from about long. 45° E. to long. 75° E. Along almost the whole of that extent the coast line is now charted, and a number of prominent peaks have been fixed. During roughly the same period the Norwegian vessel *Norvegia* was in the same waters. Their map with less detail is published in a paper by Major G. Isachsen in *Norges Svalbavd og Ishavsundersökelser, Meddelse* Nr. 12. The two maps overlap east of Enderby Land and the names are different. There was, however, an agreement between the two explorers, Sir Douglas Mawson and Captain Riiser-Larsen, made in a meeting in antarctic seas, to regard the meridian of long. 45° E. as roughly dividing their respective spheres of work. The *Discovery* thus limited her work towards the west. It is to be hoped that the confusion of two sets of new names will not be perpetuated.

Scientific Investigations in East Greenland

Good progress is reported in the Danish three-year programme of scientific investigations in East Greenland, which began last year under the direction of Dr. Lauge Koch. The entire expedition comprised 96 members and they had at their disposal two ships, twelve motor-boats and two aeroplanes. Twenty-six members of the expedition are spending the winter in Greenland: the others returned to Copenhagen on Feb. 19. According to the *Times* of Sept. 21 Dr. Koch announces that already 240,000 square kilometres of the east coast lands between lat. 70° and 77° N. have been surveyed largely with the help of aeroplanes. Important geological investigations have been carried on around King Oscar and Franz Josef fjords. During the coming winter the chief bases are to be at Scoresby Sound, Ella Island, Clavering Island and Hochstetter Sound. Each station will be provided with wireless and will serve as a base for seaplane flights as well as ground survey parties. Hydrographical investigations were also carried out in coastal waters and will be continued next summer. Biologists are attached to each field party.

Relevelling of London

The adoption of the Newlyn datum for Ordnance levels in place of the old Liverpool datum involved a change in levels on the Ordnance maps throughout Great Britain. The difference, however, is not constant owing to errors due to imperfections of instruments in the past. In certain areas surface movements may also be responsible. A network of relevelling along twenty-one lines was completed for the London area in March 1932, involving about 2400 bench marks between Hemel Hempstead and Ware on the north, Godstone on the south, Windsor on the west, and Stroud and Chelmsford on the east. The new heights, as well as the old, with the location of the bench marks, are published in advance of the sheets involved in a volume entitled "Relevelling of London, Abstracts of Secondary Lines" (Ordnance Survey 1932, 7*s*. 6*d*.) The difference between the old and new levels appears generally to be about a foot or a little more, the new levels showing the reduction.

Aerial Photography in Map-making

The progress made of late years in topographical surveying by means of aerial photography is strikingly illustrated by a recent report from the Canadian Department of the Interior. The Dominion of Canada with its vast expanse of hyperborean territory, the accessibility of which is rendered extremely difficult by the physical conditions, has proved a splendid field for this modern method of planimetry. Within the last decade, a total area of 402,500 sq. miles has been covered by aerial photography, comprising 125,000 sq. miles by vertical photographs and 277,500 sq. miles by oblique photographs. Vertical photographs are serviceable for mapping to fairly large scales, or in districts where the country is rough and mountainous, while oblique photographs are more particularly adapted to the exploratory mapping of extensive areas of forest and lakeland of fairly uniform level, such as constitute so large a proportion of northern Canada. Indeed, the oblique method is known as the Canadian method and has been adopted in other countries where the conditions are similar. Its moderate cost, flexibility and the small amount of ground surveying required render it particularly applicable to northern latitudes. During the last ten years, forty map sheets on a scale of four miles to the inch, each covering an area of 5,000–6,500 sq. miles, and three map sheets on a scale of eight miles to the inch, each covering an area roughly four times as great as the 4 mile-inch maps, have been compiled from oblique photographs and published in a National Topographic Series designed to cover eventually the entire area of Canada. Other map sheets have been issued which have been compiled from vertical photographs on larger scales of 1 or 2 miles to the inch.

The Worker's Point of View

The *Human Factor*, vol. 6 No. 8, contains an article by Mr. Louis Katin, a non-apprenticed workman, on "Craft Distinction in the Factory". He demonstrates the importance within the factory of the 'class-feeling' arising over apprenticeship. He explains the worker's prejudice against non-apprenticed companions as due to pride of craft, collective desire to produce better work than any other factory, and consequent dislike of anyone likely to lower general efficiency. He suggests that apprenticeship should be compulsory for all boys leaving school, and possible, without indentures, for those already in the industry. The employer should then make sure that each was taught by a skilled foreman. He cites as difficulties parental disapproval, the length of time involved, and the trade union and employer agreements which unduly limit the number of apprentices in some trades. Yet he thinks that the three parties concerned, consulting with the young people, should find a solution, and with the facilities now afforded by the technical schools the term of apprenticeship might be shortened. Mr. Katin deals convincingly with apprenticeship as a source of disharmony and

social differentiation amongst the workers. It would be interesting to have his opinion on the formidable social hierarchies still to be found in factory and business organisations where apprenticeship is non-existent.

University of the Witwatersrand Fire

WE are glad to learn from Dr. W. Cullen, honorary secretary of the committee formed to restore the library of the University of the Witwatersrand, which was destroyed by fire last Christmas Eve, that satisfactory response has been made to the appeal for funds and books. So far, about 6000 volumes have been despatched to the University and 4000 have still to go. Mr. J. G. Gubbins, whose name is most intimately associated with the 'Africana Collection', has been in England for several months and, as a result of his efforts, a very remarkable collection of historic material connected with South Africa and the Rhodesias has been brought together, which, if circumstances permit, will be exhibited in London this autumn. Lieut.-Commander Tufnell, nephew of Mr. Gubbins, has generously given £500 for some exceedingly rare books and prints which Mr. Gubbins has procured for South Africa. The committee has also received from the Imperial Chemical Industries and its subsidiary companies a very useful donation of 1000 technical and scientific books, and from Lord Melchett the residue of his late father's library, which numbers about four hundred volumes. The University authorities have informed the appeal committee that, though funds are limited, they have decided to start building the new fire-proof library, but will only complete it as the necessary money becomes available.

The Children's Museum in Brooklyn

THIS interesting venture made unprecedented growth and expansion in attendance and activities in 1931. The city's effort to find emergency employment resulted in a welcome temporary addition to the workers, who at one time numbered so many as a hundred. The Museum has three main aims: to give children joy and satisfaction through wholesome activity; to make their education fun; and to give them a consciousness of ability to succeed (Museums of The Brooklyn Institute of Arts and Sciences—Report for the Year 1931). It follows these aims through six divisions of activity—lectures, docentry, loans, boy scouts, mineralogy and the library—and much ingenuity is shown in the methods of laying hold of the childish interests. For example, there is the jig-saw puzzle section, where the puzzles, made in the Museum and related to the exhibits, now number 1000, and were used by 111,727 children. But this ploy demanded a preliminary, and we are told that one coloured woman, Estelle Hall, presided at the washing of 143,577 pairs of [coloured] hands in preparation for assembling puzzles and handling books. The loan division now owns 3812 exhibit cases, many boxed by emergency workers, and during the year these loans made 2,350,260 contacts in the 688 schools which borrowed them.

Extension of the Piccadilly Railway

THE Piccadilly railway originally ran from Hammersmith to Finsbury Park, a distance of 8½ miles through the centre of London. It is now being extended and on completion next year will be 25 miles long and will run from west to north across Greater London. The section from Hammersmith to Acton Town has been running for some weeks. The section from Finsbury Park to Arnos Grove, Southgate, was opened on Sept. 19. Each station with the exception of Arnos Grove is fitted with three escalators. The running of the trains will be notified to passengers by 'describers' showing the destination and the stations at which stops will be made. Although there are twelve different stations, only two connecting wires are required for operating the describers. A 2¾ minutes service will be run to and from Wood Green and a 5½ minutes service to Arnos Grove. This requires 347 trains each way between Wood Green and Hammersmith and made it necessary to provide 275 new cars. The motor cars are equipped with two 240 horsepower motors and the average speed including stops is 25 miles per hour. The electrical energy is obtained on the three phase system from the North Metropolitan Electric Power Supply Company. There are three substations each of which contains three 1500 kilowatt mercury arc rectifiers for converting the power to the direct current system required by the motors. These converters have been made by the British Thomson-Houston Company at Rugby and embody improvements. The line is equipped with automatic signals of the colour light type. These are controlled by track circuits and provided with train stops.

Announcements

IT is announced that Dr. G. C. Anderson, deputy medical secretary of the British Medical Association since 1919, has been appointed medical secretary of the Association in succession to Dr. Alfred Cox, who has retired.

THE following awards were made at the Council meeting of the Royal Aeronautical Society held on Sept. 20: Silver Medal, to Senhor Juan de la Cierva, for his work in connexion with the development of the autogiro; Simms Gold Medal, to Mr. P. Salmon, for his paper and work on catapults; Wakefield Gold Medal, to Mr. L. G. Frise, for his invention of the Frise aileron; R.38 Memorial Prize, to Mr. D. H. Williams and Mr. A. R. Collar for their joint paper on "The Motion of an Airship under Certain Conditions"; Pilcher Memorial Prize, to Mr. Dowsett, for his paper on "The Design of Aeroplane Controls and Control Systems".

APPLICATIONS are invited for the following appointments, on or before the dates mentioned:—An assistant investigator in the Safety in Mines Research Board tenable at Sheffield—The Under-Secretary for Mines, Establishment Branch, Mines Department, Cromwell House, Dean Stanley Street, Millbank, London, S.W.1 (Oct. 22). A biochemist at the Queen's Hospital, Birmingham—The House Governor (Oct. 31).

Fertility of Bees and Vitamin E *

THE question arises as to how in the bee colony certain larvæ are turned into queen bees with extraordinary powers of fecundity while the larvæ which become worker bees normally are sterile. The larvæ start equal, for both queen and worker larvæ are incubated from fertilised eggs, and it is known that a worker larva not more than three days old can be converted into a queen. The suggestion was made by one of us that the larva destined to be a queen bee was given a diet rich in vitamin E which is necessary for fertility, while this vitamin was withheld from the worker larva. The queen larva is fed solely on what is termed 'royal jelly', and when the queen is actively laying (for example, 2000 eggs a day) she is fed by her attendants with the same rich food. Royal jelly is generally accepted as being a secretion from the pharyngeal glands. Worker larvæ are supposed to be fed on royal jelly up to the age of three days when they are weaned on a diet of honey and pollen. According to von Planta (Cowan's "Honey Bee") the larval foods of the bees have the following average composition :

	Albumen. (per cent)	Fatty Substances. (per cent)	Sugar. (per cent)
Queen	45·14	13·55	20·39
Worker			
Under 4 days	53·38	8·38	18·09
Over 4 days	27·87	3·69	44·93
Average	40·62	6·03	31·51

To try to prove whether royal jelly contains an amount of vitamin E which is not present in honey and pollen the following research was undertaken :

Ten young female rats in separate boxes with their first new-born litters were put on a vitamin E-free diet on May 20, 1932. The diet was prepared in the chemical department of British Drug Houses Ltd. and a sufficiency of yeast and cod liver oil was added to keep the rats in good condition and maintain the growth of the young. It was considered that by suckling their young up to the weaning period the mothers would be drained of any store of vitamin E in their bodies; experience has shown that the power of such mothers to breed is lost by the continued feeding on the vitamin E-free diet.

On May 26 mother rats (1 and 2) with their young were given in addition each day about 2 gm. of pollen and honey, while mother rats (3 and 4) and their young received about 2 gm. of honey and pollen a day, the pollen in this case having been first soaked in honey and water for 24 hours. The rats eat the pollen and honey well. On June 27 a supply of royal jelly (queen bee food) collected from colonies about to swarm was available, and mother rats (5, 6 and 7) and their young were given about 0·05 gm. of this jelly in addition to their diet. The royal jelly was put at the back of the tongue of each rat so that it was all swallowed. It was soon realised that the supply of royal jelly would not be adequate for these mothers and their young, so on July 6 the young were removed, and the experiment continued on the mother rats alone; the young from the other mother rats were removed also. Mother rat (9) had killed her litter soon after birth: from July 6 onwards she was given in addition to the vitamin E-free diet about 2 gm. of worker larvæ bee comb, so that she got both the young larvæ and their food to eat. Mother rats (8) and (10) were kept as controls on the vitamin E-free diet without any addition from the hive.

Healthy bucks kept during the night on a normal diet of bread and milk, oats and green food, were from now onwards put to the mothers during the day time; the bucks were changed so that every mother rat had an equal chance of fertilisation.

On July 29 one of the royal jelly rats had a litter of five healthy young. She killed these after two days' suckling. The supply of royal jelly having now given out, on Aug. 3 any addition of honey and pollen was also stopped. A few days later another of the royal jelly rats had a litter of fully developed young, but killed them just after birth. One of the other mother rats which had received an addition of pollen and honey to the diet was found with one immature dead fœtus. All the others having failed to conceive, the experiment was stopped on Aug. 12. Each of the mother rats had increased in weight during the experiment, the royal jelly rats by about 25 gm. each, the others by 30–38 gm. and all were in good condition at the end.

The results show that the daily addition of about 0·05 gm. of royal jelly during one month effected the production of two full term litters among three rats, while the addition daily during two months of 2 gm. a day of honey and pollen or for one month of worker larvæ comb was ineffective, only one immature fœtus being produced among five rats.

It is proposed to continue the research next summer, but the evidence so far appears to justify the conclusion that the bees add vitamin E to royal jelly, on which queens are raised, and withhold it from worker larval food. It is surmised that the vitamin is obtained from pollen and concentrated by the workers possibly in the secretion of their pharyngeal glands, which may produce royal jelly.

These experiments may open up a new avenue of research for bee-keepers and lead to better agreement on matters appertaining to the biology of the honey bee (*Apis mellifica* L.).

The expense of this research has been met by a grant from the Royal Society Government Grant.

Constitution of Cholesterol

ON account of the biological importance of the sterols and bile acids, and the relation of the group to vitamins and hormones, particular interest is attached to a knowledge of their molecular structure; and I have recently reviewed the whole of the chemistry of these substances from the point of view of the hypothesis that the carbon skeleton of cholesterol is terpenoid, that is, made up of isoprene units with the extrusion of three carbon atoms from one of the units. It has been found possible to devise a formula which identifies the cholesterol carbon skeleton with that of

the hydrocarbon squalene less three carbon atoms, and it is believed that the new expression offers a satisfactory explanation of the complex relations brought to light by the combined work of Windaus, Wieland, Borsche and many other chemists.

It is suggested that cholesterol may be 2:6:22-trimethyl-(7:24) (8:22) (12:21) (16:20)-tetracyclo-tetracosene-$\Delta^{16:17}$-14-ol and those who care to decipher this rather striking example of organic nomenclature will find a carbon skeleton consisting of two seven-membered rings fused together as are the benzene rings in naphthalene, and again two five-membered rings, one fused to each of the seven rings, as close together as possible but avoiding the formation of any quaternary carbon atom. The secondary alcoholic group and the double bond of cholesterol may be in the usually accepted positions, but it is much better to move both groups one position to the left in the graphic formulæ as usually printed. This is compulsory in the case of all sterol constitutions on the lines of Rosenheim and King[1] and Wieland and Dane[2] and it makes the position of the hydroxyl identical in the sterol and bile acid molecules.

With this altered position of the hydroxyl group the recently proposed formula of Wieland and Dane covers the ground remarkably successfully, except that Wieland's own explanation of the nature of pyrocholoidanic acid cannot be utilised in the new system.

A more complete and yet brief account of this subject has been incorporated in a paper recently communicated to the Chemical Society, but in view of a discussion on the chemistry of the sterols to be opened by Prof. Heilbron at a meeting of the Chemical Society in December, it is thought that the protagonists will appreciate the opportunity to consider in advance the theory now put forward.

Variations of Latitude and Great Earthquakes

MILNE, Cancani and Sieberg have studied the connexion between the latitude variation and earthquakes statistically, by considering the pole shift to strain the earth; the stress called forth by the shift was discussed by Spitaler. Dr. H. Kimura has published, in recent volumes of the *Proceedings of the Imperial Academy, Tokyo*, the results of direct observations of latitude made at the international stations. Plotting the *unsmoothed* mean values of morning and evening groups of observed pairs of stars, I find sharp bends almost simultaneous with many disastrous earthquakes, as given by Prof. A. Imamura in his catalogue. The accompanying diagram (Fig. 1) for the interval 1928–31 illustrates the features—time is marked in dots, great earthquakes by x, minor world-shaking earthquakes by short transverse lines, and deep earthquakes by o.

A glance at the diagram shows that: (1) great earthquakes change the course of pole shift and mostly form angular points: (2) the effect of earthquakes is much felt when the amplitude of latitude variation is small (see the course for 1928): (3) the velocity of the pole changes before and after great earthquakes: (4) curvature is diminished before or after great earthquakes—the path becomes straight or even concave outwards: (5) deep earthquakes, though feebly felt on the surface, sometimes affect the pole shift (see 1928.39 and 1930.14).

Considering that the path before the earthquakes of Khorassan (1929.33) and Newfoundland (1929.89) was nearly straight for about two months, such subterraneous process seems to have been going on for many weeks. It therefore seems likely that there is some foreboding of the earthquake, if daily observation of latitude variation be examined; the change

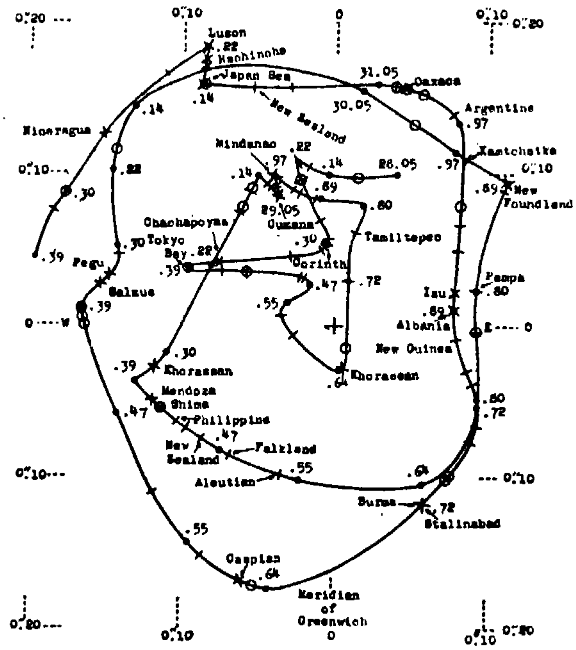

FIG. 1.

of velocity gives another hint to prediction, though the locality cannot be stated.

The readjustment of the principal axes appears sometimes to take place by roughly antipodal earthquakes. There are numerous examples, but the earthquakes of Kansu (1920.96 and 1927.39) and Mendoza (1920.96 and 1927.28), following one after another, are typical examples. If the pole be shifted by earthquakes as here described, the nutations following them are likely to be detected; if the core be liquid, it would act as a damper and make the motion aperiodic. Quantitative discussion can only be made by examining the result of daily observations, of which we have the *Berichte* of the Potsdam Geodetic Institute, but those of recent years are not yet published.

Twisted Trees—Real and Mineral

AMONG the Research Items in NATURE of July 23, 1932, p. 136, reference is made to an interesting paper on twisted trees by Knorr (*J. Heredity*, 1932, **23**, No. 2). From a systematic survey of twisting in various types of trees, the regional distribution of this deformation and the statistical data as to the clockwise and anti-clockwise twisting, Knorr discards light-tropism and influence of winds as possible causes of

this phenomenon. He concludes tree twisting to be genetic in origin, and therefore regards the lumbermen's practice of sparing twisted trees as likely to perpetuate and even enhance the existing evil. To the biologically inclined forester this naturally represents a well-cut and working hypothesis; and yet, I am not convinced.

We can eradicate every vestige of these unfortunate trees and still a new and even more luxurious growth of twisted trees may spring up in the course of time on the ashes of the old.

The solution to this apparent paradox is to be sought in the soil or rather in the fusion of heredity with environment. The tracing of an organism's form and functions to some more primitive type of organic life is basic to our conception of evolution. But unless we can extend this relationship and identify the more fundamental characteristics of living matter with the properties of its constituents—the inorganic world—and thus establish a link between these two spheres, the theory of evolution will remain a wandering derelict.

Minerals constitute an intrinsic component in every organic cell, extending from the iron and sulphur bacteria up to the highest floral and faunal complexities.[1]

The alkaline earth group together with some silicates represent the material which imparts protection, rigidity and form to living matter. This function is the direct outcome of the physical and chemical properties of these substances and therefore we may expect to find in the mineral world some primitive skeleton outline of the organic structural forms.

Actually the salts of calcium, barium and strontium as well as silicates produce arboreal growth such as creeper, bush and tree-like forms.[2]

This stabilising tendency—both in their inorganic condition and in organised matter—is undoubtedly due to the transitory colloidal state of these substances and the peculiar character of osmosis resulting from it.

A more detailed study has shown that this characteristic is even more specific and the growth is typical to each individual radicle or group.

So we find the calcium salts yield upright tree-like formations with a corrugated surface, barium salts give straight growth with a spiral surface, strontium salts form beautiful spirals of a smooth tape-like growth, whilst silicates produce bamboo-like formations.

Again, our experience with the introduction of such groupings as sulphates, carbonates, phosphates and oxalates shows that the increase in constitutional complexity of the radical combinations, especially organo-metallic associations, is followed by a remarkable impetus in arboreal growth and general functional augmentation.

The gradual substitution of these substances by one another in the organism without impairing general metabolism seems to be well established. The silicious matter of the lower organisms gave way to calcium carbonate which in its turn was substituted by calcium phosphate in the higher forms.

Our study of bacterial culture media, general nutrition and such plants as loco-weed, tobacco leaves, etc., shows that this substitution is applicable to barium and possibly strontium.

Considering all these facts it seems to me that tree twisting is primarily due to local soil peculiarities which have in course of time modified the structural constituents of the plants.

Knorr's observation as to regional distribution of tree deformation is as much in support of his genetic idea as the one presented here—his record of a balance in clockwise and anti-clockwise twisting is, however, certainly in full agreement with the view advanced in this letter.

Such an equilibrium seems to be fairly general in periodic formations and is due to boundary influences as well as progress of diffusion in the direction of least resistance. This symmetry was observed in the spiral formation of several inorganic and organic substances.[3]

Whilst emphasising this genetic rôle of mineral matter and its substitution—it is obvious that the cell adaptation to a new or modified environment becomes slower and more difficult with the increase in its differentiation and specialisation; in other words, heredity influences become more accentuated as we ascend the scale of organic life.

Heredity thus appears as a moulding, an incarnate history of successive environmental stages transmitted from the past.

Human Pathological Conditions Determined by Any One of Several Genes

IT is a striking fact that in many inherited human pathological conditions more than one type of inheritance is found. To quote only two examples, retinitis pigmentosa may be either dominant or recessive, and congenital stationary night blindness may be dominant, recessive, or sex-linked.[1] In a collection of human pedigrees of a condition showing dominant inheritance there is no possibility of determining whether a single dominant factor is involved in all cases, or whether the condition may be determined by any one of several dominant factors. This is also true of sex-linked inheritance, but in the case of a condition which behaves as a recessive, a test is available. The incidence of first-cousin marriages amongst the normal parents of affected offspring can be related to the incidence of the condition in the general population. The formula in use was proposed by Lenz[2] and Dahlberg.[3]

If a be the incidence of cousin marriages in the general population, and p^2 the incidence of the recessive defect in the general population, the proportion of cousin marriages amongst the parents of affected offspring is given by

$$\frac{a}{a + 16p}$$

The value of a may be taken as 0·008 in European communities. Hogben summarises the data on albinism collected by Pearson, Usher and Nettleship.[4] Excluding non-European cases, partial albinism, and uncertain sibships, the data fit the hypothesis of simple recessivity reasonably well. For these cases the percentage of first-cousin marriages amongst the normal parents of albinos is 17. This corresponds to an incidence of albinism in the general population of 1 in 168,000. But, the incidence of albinism in Europe is known to be of the order of 1 in 10,000 to 20,000. It is very difficult to account

for this discrepancy except by postulating that albinism is determined, not by one recessive gene, but by any one of several.

Retinitis pigmentosa presents the same phenomenon. The percentage of cousin marriages in the Usher[5] pedigrees, as summarised by Hogben,[1] is also 17. The incidence of the condition, even excluding cases determined by dominant inheritance, must be much higher than 1 in 168,000. It is to be noted that the exclusion of certain cases by Hogben cannot affect the result. The incidence of consanguineous unions is at least as high for the unselected material. This applies to albinism also. Juvenile amaurotic idiocy may be taken as a third example. In Sjögren's[6] families, the percentage of cousin marriages is 15·3, corresponding to an incidence of the condition in the general population of 1 in 130,000, again an excessively low value.

Alcaptonuria provides an interesting contrast. The data have been recently summarised by Hogben, Worrall and Zieve.[7] The incidence of first cousin marriages is 42 per cent. This corresponds to an incidence of the defect of 1 in 2,330,000. The figure of 42 per cent may be too high as it is based only on those families in which the relationship of the parents is definitely stated, but the authors point out that even if it were not too high, the figure of 1 in 2,000,000 is probably not too small for this very rare condition.

It seems very probable, therefore, that many human defects may be conditioned not only by one of two or three factors differing in their transmission, but also by one of several factors exhibiting the same type of transmission. The crucial test would be provided by the marriage of unrelated affected persons, but such marriages are, unfortunately, very rare.

The reason why it should so frequently happen in human records that the same end result may be due to one of several factors is not difficult to understand. In laboratory material, or in domesticated animals and plants, the observer is usually dealing with one strain, or with a stock in which inbreeding has taken place. In the case of human defects, on the other hand, countless observers all over the world are constantly putting on record a substantial proportion of the rare deformities occurring in a race in which random mating is the rule.

The implications, if the phenomenon is accepted as one of general occurrence, are of considerable theoretical and practical importance, but it is unnecessary to discuss them here. The value of studies on consanguinity is emphasised especially in the case of conditions that are too common for a significant excess to be expected if only one factor were concerned. It is also becoming increasingly evident that an adequate human genetic prognostication demands a close study of the individual family concerned against the background of cases recorded in the literature, these being sifted, classified and analysed by appropriate methods.

Evolution of Hormones

IT is clear that the integrative mechanism implied in the word 'hormone' or its synonyms consists of two parts: there are on one hand the cells which elaborate the specific chemical substance, on the other, the cells which respond to the presence of this substance when it is brought to them. The object of this letter is to point out that evidence exists that some at least of these linkages have been established by the evolution of a tissue responsive to a substance already produced within the organism for some other purpose or through some vagary of metabolism.

There are several examples of the apparently useless presence in relatively primitive organisms of chemical substances which in higher groups have acquired a physiological function as hormones. That adrenaline is present in certain annelids[1] is much more certain than that it has any endocrine function in this phylum. The specific substance of the mammalian posterior pituitary which causes contraction of the uterine musculature is represented even in the elasmobranch,[2] though it must be admitted that it is by no means certain that this substance has acquired a natural physiological function even in the mammal, and it is of course possible that it has some unknown function in the fish. A better example, therefore, is the presence of an oestrin in insects,[3] since the occurrence of sharply-delimited gynandromorphism makes it highly improbable that there are functional sex hormones in this class. A converse case is the vestigial survival in the pituitary of the mammal, despite the disappearance of the responsive tissue, of the substance which causes the expansion of amphibian melanophores and teleost erythrophores.[4] Moreover, there are many examples of the extension of responsive tissue in evolution; thus the ventricular muscle of the mammal has developed a sensitiveness to adrenaline which is absent in the reptile.[5] Is it too fanciful to regard the refractoriness of the genital organs of very young female rodents to stimulating hormones,[6] or of the beating heart of the two-day-old chick embryo to adrenaline and acetyl-choline,[7] as instances of phylogenetic recapitulation?

The most striking illustration for the present argument, however, is the demonstration[8] of a substance in the anterior pituitary which stimulates the development of the mammary glands in the guinea-pig and of the crop gland in the pigeon, two analogous but by no means homologous organs, which must have developed separately their responsiveness to this (apparently) single substance.

Has Physics Discarded Mechanism?

IN his British Association presidential address of 1931, General Smuts pointed out that "the older mechanistic conception of Nature is being modified". This is undeniable; but to what extent does it justify the accompanying statement that "the very basis of mechanism is undermined"? This has been repeated frequently, with applications to psychology, ethics and philosophy that are as obvious as they are debatable.

What then is the meaning of 'wave mechanics' and 'quantum mechanics'? If we define mechanisms as systems, of any kind, in which their constituent parts or factors co-operate definitely, precisely, and in most cases repetitively, in such a way that energy is transmitted, transferred, or transformed, is not some such concept not merely legitimate, but indispensable to physics, as distinct from pure mathematics, which may, or even must, dispense therewith?

To cite specific examples, are not the rotating galaxy, the solar system, crystal oscillators, vibrating atoms, and possibly also electrons and protons, mechanisms in the same sense as a clock is a mechanism? Further, if we regard any series of periodic changes as a wave series, may we not include under 'wave' a swinging pendulum, a water wave, and an electron?

It should be observed that purpose, in any form, is neither implied nor excluded, while the uncertainty principle may express only the limitations of knowledge, not necessarily the character of Nature.

Is not the 'older mechanistic conception' being replaced by the concept of mechanisms which are so much more complex, delicate and precise than earlier models that only mathematical expressions are adequate for their description and explanation? But it does not follow that, because such mechanisms cannot be imaginatively represented, they are therefore non-existent; it simply implies that they are too complicated for imagination to grasp. The advance in theory, then, does not justify the complete discarding of mechanism, as such.

Change of Paramagnetic Susceptibility due to Absorption of Light

WE have already published in NATURE[1] a note giving the results of our observation on the change in susceptibility produced in paramagnetic solutions like that of chromic chloride, etc., due to light absorption. Following the suggestion of S. Kato, we had assumed that the absorption maxima at λ 4300, 6100 in a given solution of chromic chloride were due to the transition of the Cr^{+++}ion from the ^4F to ^4G resp. ^2H state. On the supposition that both in the initial and in the final state the magnetic moment of the ion is due only to the spin moments of the magnetic electrons, such transitions would be accompanied by diminution in the magnetic moment of the ion. We reported that the result of our observation indicated a diminution in the susceptibility of the chromic chloride solution and therefore was in agreement with our theoretical assumptions.

Recently Gorter[2] reports that he has observed a similar diminution of susceptibility in a solution of chromic chloride due to absorption of light, but he finds that this diminution is to be attributed to rise in the temperature of the solution. Since the publication of our letter in NATURE, we have found that the deflection of the bulb containing the chromic chloride solution corresponded to an *increase in its paramagnetic susceptibility* and not to a diminution. A paper containing the results of our investigation was sent about two months ago to the *Zeitschrift für Physik*, where the experimental details will be found. We may mention here that we used a torsion balance of period 3–5 sec., and neutralised the effect of the field on the bulb containing the concentrated solution, by attaching a bismuth ball of suitable size below it. The response to the incident light was almost instantaneous, and after a prolonged exposure the light spot gradually returned to its original position and then moved over to the opposite side. Specchia[3] has also observed this quick increase in magnetic susceptibility due to light absorption.

In using the torsion balance, the bulb has to be placed almost in a position of instability in the inhomogeneous magnetic field, and for each set of observations a new adjustment has to be made. Under such conditions it is difficult to obtain reproducible results. We have, therefore, tried other methods of making this effect measurable. The following one we think will give fairly consistent results. A modified form of the inclined capillary tube arrangement used by Liebknecht and Wills[4] is filled with chromic chloride solution and the meniscus is placed between the pointed poles of an electromagnet. Light from a mercury arc, after passing through an infra-red filter, is focused from the top on the meniscus. Observation of the position of the latter in the magnetic field is made, once when the incident light from the arc is further filtered through a concentrated solution of chromic chloride, and again when this filter is taken off. Deflections of about 1·5 scale divisions of the micrometer scale in the eye-piece of the observing telemicroscope, indicating an increase of susceptibility, were noted.

Since the transitions from the ^4F to the ^2G resp. the ^2H state represent diminution of the spin moment of the ion, the observed increase in susceptibility can only be interpreted as being due to the temporary break down of the l-coupling between the Cr^{+++}ion and the associated water molecules. Some interesting applications of this result are given in another paper which appears in the *Zeitschrift für Physik*.

Iodine in Cod Liver Oil

THE purpose of this note is to indicate to British workers in the field of endocrine secretions and nutrition certain experimental work which we have thus far withheld from complete publication pending studies which we are now ready to report in detail.

We showed[1] that ferrous iodide mixed with the food would benefit rats on a diet deficient in vitamin A. Later we demonstrated that unsaturated fatty acids were apparently indicated in addition.[2] More recently we have summarised our findings.[3]

Studies made during the past winter and spring in which we induced leg-weakness in chicks by the intravenous injection of anterior pituitary extract, but prevented it in other animals by orally adminis-

tered thyroid extract, have led us to interpret correctly the findings of a poultryman who reported to us the remarkable success secured by him in administering iodine to a number of chicks that had developed leg-weakness on a diet apparently adequate so far as cod liver oil and fish meal were concerned, but containing an excess of wheat. In an extensive report, which will shortly appear in *Endocrinology* (Chidester, Ashworth, Ashworth, and Wiles), we are describing our results, which seem to emphasise the rôle of the iodine in cod liver oil in the prevention of rickets. We suggest that since ergosterol and ultra-violet light may induce excess calcifications and even set up a profound calcium-iodine unbalance, it may be wise to utilise cod liver oil, which we have found it possible to super-iodise and otherwise mineralise in the treatment of certain diseases.[4] Several investigators, including our group, have shown that iodine will prolong the lives of rats that have had an excess of vitamin D.

We have already credited (loc. cit.) Col. McCarrison with his initial emphasis on the iodine-fat balance in nutrition, and consider ourselves fortunate in having been able to point out the rôle of ferrous iodide and unsaturated hydrocarbons and fats in several so-called vitamin deficiencies. We are especially interested at present in the fact that a variety of substances of benefit to the organism can be carried into the cells by cod liver oil. We are attempting to have others repeat our observations and make clinical tests with super-iodised cod liver oil in tuberculosis and the common cold and also to compare the results obtained in leprosy with ordinary chaulmoogra oil, with those secured by iodising it.

If our studies are significant—and we believe that long-continued experimentation makes them so—we have evaluated the rôle of the iodine of cod liver oil in the treatment of nutritional diseases and furnished an explanation of the activity of many iodine-containing medicaments.

Causes of Ionisation in the Upper Atmosphere

SINCE May 1931, I have taken numerous measurements of the virtual reflection height of radio waves 40–140 m. long; at the same time, I have, at different times during the day, determined the short wave limit for vertical reflection in the ionosphere. Some of the principal results which I have obtained are summed up here:

In the E region, by day, the maximum electronic density does not exceed 6×10^5 (electrons per c.c.) in summer, and $3{\cdot}7 \times 10^5$ in winter.

In the F region, at sunset, the maximum electronic density is 9×10^5 in summer, and 6×10^5 in winter.

After sunset, in the E region, the maximum electronic density varies irregularly, since there are sometimes remarkable increases, even several hours after sunset. These happen when barometrical depressions occur at the place of observation or to the north of it.

In the F region, during the night, the maximum electronic density is sometimes observed to be decreasing regularly, which made it possible to calculate a value from 1×10^{-10} to 2×10^{-10} for the coefficient of ionic recombination; at other times, on the contrary, rapid increases of the maximum electronic density are noticed, which are followed by diminutions, and that also for many times successively during the night.

The increases of ionic density in the E and F regions appear by no means connected with one another.

Corresponding with perturbations in the earth's magnetic field, the virtual reflection height in the F region is increasing: no perceptible variation occurs in the E region.

During the solar eclipse of Oct. 11, 1931 ($13^h\ 6^m$ G.M.T.) not visible in Italy, I observed a perceptible diminution of electronic density in the E region and in the F one.

These facts can be explained by admitting the arrival, in the ionosphere, of electrons from the sun, which would invest even the shaded hemisphere (after A. Dauvillier's recent theory[1]).

Chapman's theory[2] (concerning the arrival of swiftly moving particles) does not appear to interpret easily the night increases of ionic density and the magnetic correlations regarding the F region alone.

Ball Lightning

ON the afternoon of Aug. 31 I was at Portofino watching across the bay a succession of heavy thunderstorms that drove up from the south over the Ligurian hills east of Rapallo. At about 3.30 P.M. a rain-curtain a couple of miles wide was moving northwards, completely obscuring a section of the coast-line. While this was opposite Chiavari two appearances of 'ball lightning' were seen by myself and two companions. (A third earlier one of brief duration was seen by one observer.)

Lightning flashes were frequent: at the time mentioned the rain curtain was pierced by two independent vertical flashes, one-half to one mile apart, which appeared not to reach the ground (or sea). Then, in the gaps between the lower ends of the flashes and the ground, two brilliant stationary lights appeared, lasting about five seconds in one case and at least eight seconds in the other, as though two powerful arc lights had been turned on. In both cases a second or so was required to attain maximum brilliancy, which was then maintained constant until the last second or so when the lights gradually dimmed and suddenly went out. This change in light intensity at the beginning and end may have been due to variation in thickness of the obscuring rain curtain. No specific sound was associated with the phenomenon, but this may have been due to the distance (probably ten miles) and to the almost continuous roll of thunder at the time. That the 'ball' discharges appeared stationary may also have been an effect of distance.

I have had no opportunity to inquire whether any record of these facts has appeared in the Italian Press or meteorological reports.

Research Items

Co-operation in Dahomey.—Mr. Melville J. Herskovits publishes in *Africa*, vol. 5, No. 3, a study of Dahomean ethnology, based on field-notes collected during a trip to Dahomey, Nigeria and the Gold Coast in January-September, 1931. The civilisation of Dahomey is based upon an agricultural economy. Everyone must know how to cultivate the ground, whatever his rank. Women play an active part in economic life, cultivating, harvesting and marketing the crops. There is a class of 'free' women, due to this economic activity, who play the rôle usually assumed by men as the heads of families and become titular 'husbands' to their 'wives'. Dahomean men are organised into family vocational guilds, working in iron and brass, weaving cotton, etc., an exception being wood-carving which is an avocation exercised by all who have the necessary skill. The women's contribution to the crafts is the making of pottery, which is organised in districts according to the distribution of suitable clay, rather than in families, the guild organisation, however, persisting as in other vocations. The co-operative aspect of organisation pervades all Dahomean economic activity. The major expression of this is the *Dokpwe*—a term applied equally to the organisation and to the individual member. It is neither a guild nor a society, but is regarded as a 'force', the man power of Dahomey, as it embodies all 'young' men. The control is vested in an official known as the 'Chief of the Dokpwe' who is concerned not only with the control of the men under him in communal tasks, but also with funerals. The working of the organisation may be illustrated by the following example. If a man is ill at the time of the clearing of the fields, the Dokpwe will clear his land for him as no member and his family must be allowed to starve. It is, in fact, an association for mutual aid, so important that no man may be exempted from its call. If a man, even the king, in going along a path, sees a Dokpwe at work he must explain his errand and ask leave to proceed.

Central American Eccentric Flints.—The character and distribution of the so-called 'eccentric flints' of Central America are discussed by Capt. T. A. Joyce in his presidential address to the Royal Anthropological Institute, 1932 (*J. Roy. Anthrop. Inst.*, vol. 62, pt. 1). They are found, so far as known at present, only in the area occupied by the ancient Maya, an inverted triangle with its base lying between Palenque and Belize on the north and its apex at Copan in Honduras. Their meaning is obscure; their technique equals the finest products of prehistoric Denmark and is surpassed only by the finest 'ripple-blades' of Egypt. They are generally associated in groups, occasionally in graves, more often under sculptured stones bearing a date which can be related to our chronology. For example, the British Museum expedition to Pusilhá discovered a deposit of nearly one hundred examples of flint and obsidian under a stela which may be placed at about A.D. 202 (or three hundred years later according to the American scheme of chronology). The large series now in the British Museum shows that these flints can be classed according to type. They served no utilitarian purpose, and are purely ceremonial. The main types are 'blade' type and derivatives—winged, waisted, flanged, cruciform—the 'scorpion' type, the 'centipede' type and 'annulets' and 'crescents'. Some have been flaked to represent human heads; while recently a series of engraved obsidian flakes has been discovered at Tikál, which show the figures of the Maya gods in the style of the Dresden codex. Chert was used as well as flint and obsidian, the source of the last being, probably, Guatemala. The 'eccentrics' suggest several problems, for which at present there are no solutions. They seem to have been deposited in groups as 'foundation deposits' on sites of importance. Each group seems to include every variety in every stage of construction, and no single specimen shows signs of wear on its edges.

Redwing Breeding in Scotland.—More than once, in the northern counties of Scotland, it has been suspected that the redwing (*Turdus iliacus*) may have nested, for birds have been heard singing long after the spring emigration to the usual nesting haunts in Scandinavia and northern Europe had ceased. But only now has confirmation of this supposed extension of range been found (*British Birds*, Sept., 1932, p. 132). In the Moray Faunal Area (for obvious reasons no more definite locality is given) A. H. Daukes saw a pair in early June and later discovered the nest with six eggs in a solitary beech tree. Unfortunately about this stage the nest was robbed, probably by a rook, but the discovery of the greater part of the shell of one egg upon the ground helped, along with the nest, to confirm the identity of the birds. There is perhaps nothing very remarkable in the fact that a bird, common in Scotland and indeed considerably farther south in the winter, should have remained to nest, instead of departing for Norway or the Baltic provinces, but the first authenticated record of breeding in any part of the British Isles has its own special interest and may be part of a general extension of range southward which has been noted in other species.

Development *in vitro*.—C. H. Waddington (*Phil. Trans.*, *B* vol. 221, pp. 179–230, 1932) has cultivated *in vitro*, by the watchglass method, entire blastoderms of chick and duck removed from the egg during the first two days of incubation. Under the conditions of these experiments a chick embryo will remain alive for two to three days and during this time pursues its normal course of differentiation, except that the rates of differentiation and of growth are considerably slower than *in vivo*, the rate of growth being the more affected by the unusual conditions, so that embryos are obtained which are much too small for the stage of differentiation which they have reached. The results of experiments on the presumptive organ-forming regions are described, using blastoderms with a well-formed primitive streak but no head process, which were cut into portions transversely at various places along the primitive streak. The isolated endoderm has not been successfully cultivated. Isolated epiblast, cultivated from young or medium primitive streak stages, yields neural groove, notochord, somites, etc. Two epiblasts, cleaned of endoderm and placed so that their mesoderm faces were in contact, were cultivated and both developed neural grooves, but the lower soon died and degenerated. A normal neural groove may induce an extra neural groove in the other epiblast.

Fragments of the primitive streak, cleared of endoderm, were grafted between the endoderm and epiblast of other blastoderms of similar age, the epiblast not being cut in the operation. Anterior pieces of the primitive streak give rise to neural tissue, notochord and somatic mesoderm; middle pieces give rise to mesoderm, with or without neural tissue; posterior pieces probably never give rise to neural tissue.

Commercial Drying of Wheat.—In view of the probable future extension in the use of the combine-harvester machine in England where the climate renders the use of a drier advisable, the second report (No. 25) on the drying of wheat, issued by the National Research Council, Canada, should prove of particular interest to progressive farmers in this country. The report, which is a continuation and extension of that issued in 1929, deals with the effect of different conditions during the drying process on the subsequent milling and baking qualities of the wheat. The temperature of the hot air used and its rate of flow are factors of the first importance. Since the rate of drying increases with the heat content of the air per unit time, raising the temperature or increasing the speed of flow will dry the grain more rapidly. Beyond a certain point, however, fast drying is to be deprecated since it affects the baking quality adversely. In general, 180° F. is the highest temperature that can be used with safety and even this may cause injury if the rate of flow is too rapid. The temperature attained by the wheat during the drying is another factor that seems to be connected with baking quality. Over-drying or too rapid drying are the main causes of high grain temperatures, a condition which results in impaired baking properties. Milling quality, on the other hand, was unaffected by drying under the different conditions tested. Commercial drying must of necessity be carried out under widely different climatic conditions, and it is satisfactory that tests showed no detrimental effect on the baking quality of the wheat when drying was carried out in cold weather or with humid air.

Virus Diseases of Plants.—Dr. J. Caldwell has published the third of a series of investigations into the physiology of virus diseases in plants (*Ann. App. Biol.*, vol. 19, No. 2, pp. 144–152, May, 1932.) The aucuba mosaic disease of tomato behaves very differently on *Nicotiana glutinosa* and *Datura stramonium* from what it does on *Solanum lycopersicum*. It is very interesting that the virus multiplies very little in the leaves of *N. glutinosa* and does not spread far from the region of inoculation. *D. stramonium* is a 'carrier' and shows no symptoms, but the virus spreads to all parts of the host. An interesting demonstration that rupture or damage of a tissue must take place before virus can infect was given when it was shown that the intercellular spaces of a leaf of *N. glutinosa* could be injected with virus juice without any infection taking place. The damaging of any cells by rubbing the surface of the leaf immediately brought about infection.

Viscosities of Drilling Muds.—Messrs. H. A. Ambrose and A. G. Loomis contribute an article to the *Oil and Gas Journal* for July 7, in which they seek to show that, contrary to prevalent ideas, rotary drilling mud (such as a clay mixture) is not truly viscous. The resistance of mud to flow as expressed by whatever viscosity it may possess, determines the ease with which it may be pumped, and its ability to carry up cuttings and gas. These drilling muds do not have viscosities which are constant at constant temperatures, since this function tends to vary not only with its previous treatment, implying mode of preparation, but also with the shearing stress applied to it. The muds must be regarded essentially as suspensions of clay in water, and consequently the ordinary laws governing the motion of a truly viscous liquid are scarcely applicable. The authors deal with the subject from the point of view of flow in colloidal suspensions, and the mechanism of such flow. They touch on the mathematical analysis involved, and also on certain types of viscometers which have been used for determining this alleged viscosity.

Fatigue of Zinc-coated Steel.—When an iron or steel bar is subjected to repeated stress it breaks under a stress less than its statical breaking stress if the lower stress is repeated often enough. The 'fatigue cracks' which lead to the breakdown are found to originate in pittings on the surface due either to bad finishing or to subsequent corrosion. To prevent corrosion the iron or steel may be galvanised or have zinc deposited electrolytically on its surface and the effect of each of these processes on the durability of the specimen under repeated stress has been investigated by Messrs. W. H. Swanger and R. D. France at the Bureau of Standards and their results appear in the July issue of the *Journal* of the Bureau. Both the loaded beam and the stretched rod methods of test were used, and the specimens were either polished or pickled for galvanising or galvanised or stripped again or electroplated. The fatigue limits of the electroplated specimens were higher than those of the uncoated, those of the pickled, galvanised and stripped were lower than those of the untreated specimens. The authors ascribe this difference in the effects of the zinc coatings to the hardness of the layer of zinc put on by the galvanising process.

Conduction Phenomena in Oxide-Coated Filaments.—The quantum-theoretical study of semi-conductors and rectifying contacts has been developed independently by several workers during the past year. In a paper in the September *Proceedings of the Royal Society* R. H. Fowler and A. H. Wilson apply the theory to the case of conduction in the oxide layers used in dull-emitting cathodes. They calculate current-voltage characteristics which show the general features of the experimental curves—namely, a steep initial rise of current with voltage followed by a flatter portion and a further steepening. In order to explain the form of the i/v curves at the lower voltages they assume that part of the current is electronic (and described by the above analysis), the remainder being electrolytic and approximately ohmic. The authors consider that work along these lines may be developed to account for the lack of saturation observed in the thermionic currents from oxide-coated filaments.

Cosmic Ray Particles.—The *Physical Review* of Aug. 15 contains a further communication by C. D. Anderson on the cloud-chamber photography of cosmic ray particles. The method and results may be compared with those described in the preliminary publication of Blackett and Occhialini (NATURE, Sept. 3, page 363). The advantage of allowing the cosmic ray itself to set off the expansion is evident, since, in Anderson's work, of 3,000 random expansions only 62 gave measurable cosmic ray

tracks. Anderson, using an iron-core magnet, applied a magnetic field much larger than was possible with Blackett and Occhialini's air coils. The most significant difference between the results is the much larger proportion of particles with high energies (above 500×10^6 volts for electrons or 200×10^6 volts for protons) obtained by Blackett and Occhialini. Such particles were quite rare in Anderson's work. At first sight it appears that the Blackett-Occhialini apparatus may tend systematically to miss particles of low energy, or that their estimates of the high energies may be incorrect since they used small magnetic fields. It is important that this divergence should be explained, particularly as the particles of high energy are inconsistent with Millikan's views of the origin of cosmic rays by atom-building. Anderson observes associated pairs of tracks rather frequently, and one of these tracks is always an electron. He ascribes these pairs to disruption of a single atomic nucleus by the cosmic ray and he maintains that these can be explained without postulating neutrons in the cosmic ray stream. He also observes the scattering of the particles in a lead diaphragm. In the same number of the *Physical Review* W. F. G. Swann points out some consequences of assuming that the primary cosmic rays are electrons of very high energies. He suggests that such electrons may be incapable of ionising and may only occasionally give rise to secondary particles. He examines certain asymmetries in the distribution of the secondaries over the earth's surface, assuming that they are particles of energies of the order 10^9 volts.

Corrosion Resistivity of Metal.—Reference was made in NATURE of Aug. 13, p. 245, to a method devised by Mr. Zehnowitzer for determining the velocity of metallic corrosion, based on changes in the conductivity of the corroding liquid. In a letter to the Editor, Mr. F. C. Smith directs attention to a rather similar method worked out some years ago in the laboratory of the Gas Light and Coke Company, and described in a paper published in the *Transactions of the British Junior Gas Associations Joint Proceedings* (Vol. 18, 1927–1928). The special problem under investigation by Mr. Smith was the rate of attack of different varieties of iron by water saturated by carbon dioxide, in the absence of oxygen. The measurements themselves have special importance for gas technologists, but the procedure, which appears to be little known outside the gas industry, may interest a wider circle. The corrosion was carried out in a conductivity cell furnished with the usual platinised platinum electrodes and joined to a Kohlrausch bridge; as the carbonic acid attacked the iron specimen, liberating hydrogen, the formation of ferrous bicarbonate produced a marked drop in the resistance, which, in one experiment, fell, in the course of 6 hours, to about one-third of the initial value. The resistance-change, which blank experiments showed to be solely due to the action of carbonic acid on the metal, proved a convenient measure of the rate of attack. The precautions necessary for good results included a careful control of temperature, the use of water redistilled from permanganate and the strict exclusion of oxygen. The numbers obtained for a series of irons indicate that the anaerobic attack upon iron by aqueous carbonic acid increases with the sulphur content of the metal, although other elements appear to influence the result.

Astronomical Topics

Comets.—Periodic comet Brooks (2) was detected on its return by Prof. G. van Biesbroeck at Yerkes on Sept. $25^d 8^h 14 \cdot 6^m$ U.T., R.A. (1932·0) $0^h 46^m 13 \cdot 8^s$, N.Decl.2°55′10″, mag.12·0. The comet was discovered in 1889 and found to have been very near Jupiter in 1886, when its orbit must have been greatly altered. It was seen again in 1896 and 1903, after which there were no certain observations until 1925; it is doubtful whether a single observation made in 1910 belongs to it. It had again approached Jupiter closely about 1921, but the calculations of Prof. Dubiago led to its recovery. Both he and Mr. F. R. Cripps calculated the present return; their results were almost identical, but the date of perihelion resulting from the above position is Oct. 9·49 U.T., which is about two days later than the prediction. It may be found by going 0·31 of the way from the second ephemeris in the B.A.A. Handbook to the first one. The present apparition is the most favourable possible, opposition coinciding with perihelion. The comet is 1932 *m*; it is the first time that there has been a comet *m*.

Copenhagen Circular 403 contains the following elliptical orbit of the comet Peltier-Whipple from Copenhagen observations of Aug. 10 and 24 and Sept. 9.

T	1932 Sept. 1·86128 U.T.	
ω	38°28′ 31·5″	1932·0
Ω	344 30 35·4	1932·0
i	71 42 32·6	1932·0
q	1·037175	
e	0·976172	
Period	287 years	

Harvard Card 240 announces that Dr. A. D. Maxwell has found elements which are almost the same as the above, though the observations used were all different; the arc in each case is a month in length. There is no comet in the catalogues that seems likely to be the same. An ephemeris was given in NATURE of Oct. 1, p. 513, which is near enough for finding it. It is now about magnitude 12.

Solar Corpuscular Rays.—A letter from Mr. H. P. Berlage, Jr., of the Royal Magnetical and Meteorological Observatory, Batavia, proposes the question: Are the solar corpuscular rays producing auroræ and magnetic storms identical with the solar component of ultraradiation? He states: "Now that converging evidence points to a corpuscular nature of the ultraradiation, what arguments exist against simply identifying the solar corpuscular rays, which cause auroræ and magnetic storms with the solar component of ultraradiation? The suggestion is that different stars emit differently penetrating ultrarays, and the question, why no appreciable solar component could be detected reduces to stating the fact, that the solar ultraradiation is stopped in a height of 100 km. above the surface of the earth". But this seems to amount merely to giving a name, usually reserved for rays with the great penetrating power needed to reach the ground, to rays of such inferior penetration as to be stopped at 100 km. height. This is very far from being an 'identification', and the suggestion seems to add nothing material to our knowledge.

Training of Electrical Engineers

AT the International Congress of Electricians held in Paris last July, interesting papers were read by various authors describing the training given in their countries to young men desirous of qualifying for the higher posts in the electrical engineering profession. It appears that, as a rule, the degree of B.Sc. in engineering, or its equivalent, is given after going through a three or four years' course in a technical school or college. It is impossible in the workshops of a college to give a student that insight into methods of management and actual operating that can only be obtained in works offering machinery or apparatus for sale. Hence engineering graduates or those possessing recognised diplomas have to undergo a special apprenticeship course in works, railways, power or distributing stations or with communication companies in addition to their academic training.

These apprenticeship courses are usually at least a year in length. It is highly advisable that there should be a close connexion between works and college staff, to whom most of the outgoing students have to look for advice as to the course they should follow. There is naturally a close connexion between many works and engineering colleges. The supervisors of the apprentices make their own choice and are not necessarily impressed by the academic qualifications of the young men they interview. They have to choose men whom they think will qualify rapidly for staff posts. Large companies who take a number of higher apprentices every year take only a limited number from any one country or from any one engineering college. Trade considerations in Great Britain and other countries make it advisable to take overseas students and foreigners. Several of these firms pay their graduate apprentices, generally called 'student apprentices', a weekly wage varying from 10*s*. to 50*s*., but some ask for a premium which is generally more than paid back by a weekly wage. This appreciably lightens the present somewhat onerous burden of the cost of living.

Most of the papers read at the Paris meeting dealt with the syllabuses of training colleges for the early part of the engineering training of students. It seems generally recognised that in the present economic conditions throughout the world and the very varied requirements of engineers in the different branches of the industry, it is necessary that the syllabus should not be overburdened with subjects. In Norway it includes architecture, political economy and finance. In Sweden national and political economy, technical hygiene and the building of edifices are taught. In Poland special stress is laid on methods of electrifying the country with a view to its future prosperity. In Italy, radio technology is in the front rank. It has been introduced into the programme of every industrial school. In the University of Bologna there is a two years post-graduate course for radio engineers. The degree of Ph.D. is awarded for physics and for mathematical physics. Special importance is attached to photo-electricity, television and the technique of radio-telegraphy and telephony. In Spain and many other countries stress is laid on long distance communication by telephony through wires and through space. Technical teachers everywhere are fully aware of the importance of the rapid and spectacular advances in methods of communication between distant stations which have been made during the last few years.

An interesting paper on electrical education in the United States was communicated by Prof. A. E. Kennelly. He divides training institutions into two groups, the collegiate group and the industrial group. The first contains universities and technical institutes of university rank; the second includes the research and training schools of industrial organisations, technical institutes, and professional, commercial, and correspondence schools. Actually there are 150 schools of collegiate type in the United States. These give full instruction in electrotechnics. In addition, there are 750 other schools which give partial courses in the subjects connected with electrical engineering. The complete electrotechnical course usually lasts four years. During the last two years of the course, students can specialise in transmission and distribution of energy, electric traction or electrical communication, but no two engineering colleges in the United States have identical programmes. In 1893, a society was founded for the advancement of technical knowledge. It has now 2,250 members, practically all of whom are professors or teachers in technical schools. Their judgments and decisions influence greatly the nature of the syllabus adopted by a college.

A certain number of American colleges give 'sandwich' courses of training, half the time of the students being spent in college and the other half in works. The student spends a certain number of weeks in works and a certain number in college alternately, the length of the cycle varying between two weeks and a year. For students who wish to take up 'heavy' engineering, this system has advantages. The practical work shows how important theory is and hence students pay closer attention to theoretical work. Some of the large colleges have a regular college course for four years for some of their students and simultaneously a sandwich course for others. One of the advantages is that the college can take more pupils and thus the overhead charges are reduced. There is a great variety of colleges of all kinds in America. Prof. Kennelly thinks that it would be a calamity not only for the United States but also for the world if any of these colleges cease to exist. The disappearance of a good school, whatever its type, may mean that those students who had intended to enter it must either go to some other college which is not so attractive to them or else seek to acquire their scientific knowledge by experience and private study, a method sometimes successful but more often leading to a great waste of energy.

Prof. C. L. Fortescue read a useful paper on the education of electrical engineers in Great Britain. Those students who intend to qualify fully as engineers in Great Britain usually leave their secondary or public school at the age of eighteen years, spend three or four years at a university or technical college and finish up with two years as a 'student apprentice' in works, power stations or railways. It will be seen that the training is an expensive one as during the five or six years the student is not self-supporting.

In Great Britain, the Institution of Electrical Engineers looks after the interests and maintains the standard of the profession as a whole. It divides

young electricians into two groups, students and graduates. The students of approved colleges and apprentices and assistants in engineering works can become 'students'. When a student has passed certain qualifying examinations and has attained the age of twenty-one years, he can be elected a graduate. A graduate, however, is not a 'chartered electrical engineer'. This status can only be attained after his training and experience exceeds seven years, two of which must have been in a position of superior responsibility in the profession. He has to send in an election form signed by five members and giving a complete account of his training and experience, which is scrutinised by an election committee. He must also be twenty-six years of age. When he fulfils all these somewhat onerous conditions, he is elected an associate of the Institution, and can call himself a chartered electrical engineer.

It will be noticed that there is a discontinuity in the training of an electrical engineer, namely, the gap between the university or technical college and works. Most students have no connexion with engineering and so have to make their own arrangements with manufacturing firms. Naturally, they want to go to the best-known firms, but it generally happens that these firms have already all the student apprentices they want. Hence they have to try to get into works about which they know nothing.

This has led to the adoption by a few colleges of the 'sandwich' system of training. The best-known of these colleges is Faraday House, London, which was founded more than forty years ago and now has about four hundred students. The course lasts for four years. The first year is a purely collegiate course in general engineering. During the second year the student is apprenticed under supervision to a mechanical engineering works either in Great Britain or abroad, the college making all the arrangements for him. The college is affiliated with 170 works and railways in Great Britain and abroad, for teaching purposes. Advanced theoretical training is given in college during the third year, and for the final year the students go to electrical manufacturing works and power stations throughout the country and to railways, and communication companies, etc. Those who have passed successfully through the course, several of whom also take the London B.Sc. (Engineering), receive the diploma which enables them to become graduates of the Institution of Electrical Engineers without further examination. The advantage of the system is that the student is under the same supervision throughout his course.

The recent extension of research laboratories in connexion with works has led to a limited demand for men who have done post graduate research work in university laboratories. These men usually write theses which h[illegible] them to get the higher degrees of M.Sc., Ph.D. and D.Sc. Research laboratories also take young graduates whom they train specially in their own methods of research so as to qualify them for posts on their staff.

A.R.

Solid Solutions and Liquid Mixtures

THE discussion arranged in Section B (Chemistry) on Sept. 6 at the York meeting of the British Association, was finally divided into two parts as it was agreed that the differences between solid solutions and liquid mixtures were too great for the subjects to be covered usefully in a single discussion. Prof. C. H. Desch in his paper on re-arrangements in the solid state referred to the importance of solid solutions in metallurgy and said that systems in which a series of solid solutions, stable at high temperatures, resolves itself into two or more phases on cooling are of frequent occurrence. Such systems are of two types. In the first, and most usual, the change takes the form of the separation of a new phase from solution in the same manner as the crystallisation of a salt from water. A solubility curve can be drawn and eutectoid structures similar to the eutectics produced from liquid solutions are produced. Familiar examples are the iron-carbon and iron-nickel systems, and analysis of the constituents shows that a definite migration of nickel has taken place in the solid phase. In the second type of re-arrangement which has been observed in recent years, a solid solution homogeneous at high temperatures and having the solute atoms statistically distributed throughout its lattice assumes a new arrangement on cooling through a certain point, the solute atoms taking up regular positions and so forming a super-lattice. The change is reversed on heating. A typical example is furnished by the gold-copper alloys. The equilibrium is attained very quickly and the change can be followed by electrical resistance tests. Magnesium-cadmium alloys give a similar series and the changes are at present largely unexplained although the number of such systems may be considerable.

The discussion on mixed liquids was opened by Prof. Irvine Masson who indicated that its scope is limited to mixtures of non-electrolytic fluids. The main chemical interest in such liquids lies in the formation of inter-molecular compounds but Prof. Masson pointed out that before deviations of liquid mixtures from an ideal mixture law can be interpreted as evidence of chemical interaction or compound formation, the effects of the other possible causes of combination between either similar or dissimilar molecules must be disentangled, namely, the van der Waals' cohesion forces and electrical coupling between polar molecules. In each of these alternatives as in chemical combination we have also to contemplate the reverse process of dissociation. In actual fact van der Waals' cohesion is present in every mixture of any two liquids. Electrical coupling between polar molecules occurs in all mixtures except the 'normal' liquids. Thus where chemical combination occurs it is invariably accompanied and complicated by the other two forces.

Discussing the criteria for a normal liquid Prof. Masson pointed out the danger of assuming that those liquids are normal which when mixed together give straight line property-composition curves. The use of the Ramsay-Eötvös rule concerning surface energies, Trouton's rule concerning latent heats, and Debye's polar moments, leads to the characterisation of a normal liquid as one the molecules of which remain sufficiently independent to attract one another by no forces other than the van der Waals' cohesion which they show in the vapour state. A normal liquid thus has the characteristics of a non-polar but imperfect gas. For properties such as specific volume, viscosity, vapour pressure and heats of mixing, all of which are strongly influenced by cohesion and give

indirect measurement, fundamentally, of inter-molecular cohesion, the simple mixture law does not hold. We are dealing with two opposing actions, the influence of the cohesion of each kind of molecule with others of its own kind being attenuated by the dilution, while on the other hand the attenuation is counteracted, more or less, by the mutual cohesion set up between the two kinds of component molecules. We cannot state precisely what the normal behaviour of mixtures of two non-polar substances would be but the deviations from the straight line due to cohesion reach their maximum, for a given pair of components, at a composition not far from equi-molecular.

With regard to electrical coupling between polar molecules, after referring to the view which attributed the van der Waals' forces to transient polarisation of non-polar forces Prof. Masson pointed out that as before the magnitude of the deviation depends on two opposed influences. In addition while the end-to-end coupling of polar molecules gives a complex of larger electric moment, in the side-by-side coupling the two individual polarities tend to neutralise each other, and accordingly caution is required in interpreting data for electric moments. Quantitative interpretation of the cohesions displayed by polar molecules is very difficult and Prof. Masson considers that Langmuir's presentation of the mutual cohesions of compound molecules as additive functions of their chemical constituents is inadequate. Evidence based purely on deviations from the mixture-law which might be accounted for by the relatively strong deviations due to mutual dipole cohesion is accordingly insufficient to establish the formation of chemical compounds, short of the isolation of a solid compound with distinctive properties.

Prof. G. Kendall in his paper on compound formation in liquid mixtures classified compounds existing in liquid mixtures in two types, addition compounds and substitution compounds. In the former, of which acetic acid-aniline forms an example, there is a definite increase in molecular complexity and a wide deviation in physical properties from the mean of the components. In the second type, of which phenol-cresol is an example, there is no increase in molecular complexity and the physical property-composition curves are more nearly linear. Formation of compounds of the first type depends mainly on the diversity in electrochemical character of the radicals of the components, the extent of compound formation increasing with such diversity. The reverse holds with compounds of the second type, similarity in the radicals being the dominant factor, part of the associated molecule being replaced by essentially equivalent groups. The results of a detailed examination of the two ternary systems ethyl acetate-water-alcohol and ether-water-alcohol were discussed in relation to these generalisations.

Discussing dipole association in liquid mixtures Dr. N. V. Sidgwick pointed out that in contrast to non-associated substances, associated substances give a molecular polarisation curve which rises to a maximum and then falls with increasing concentration; with non-associated substances the molecular association decreases from infinite dilution as the concentration increases. The dipole association may be due to an orientation of the molecules by the dipole forces, or to their polymerisation, and molecular weight determinations and determinations of the molecular polarisation enable the degree of association, x, to be calculated on the assumption that non-polar double molecules are formed. Thus the values of x obtained for nitrobenzene, which has a molecular polarisation five times as great at infinite dilution as in the pure liquid, by electrical and cryoscopic methods in benzene agree roughly up to about $2N$. solutions (0·46 by polarisation, 0·57 by cryoscopy). The mass-action association constant rises considerably from 0·26 at $0{\cdot}1N$. to 0·39 and 0·77 at $2N$. showing that the association is not due to a definite polymerisation but to an orientation of the polar molecules which diminishes their activity. The values of x obtained for nitrobenzene in different solvents, decrease with the dielectric constant of the solvent as is shown in the table below:

Solvent.	Dielectric constant.	x at $1N$.
Carbon disulphide	2·63	0·353
Benzene	2·29	0·313
Carbon tetrachloride	2·24	0·284
Cyclohexane	1·88	0·269

Oceanographic Instruments*

THE most complete survey of the physical oceanography of an ocean was carried out by the German research vessel *Meteor* in the South Atlantic. The plan of the expedition centred largely upon discovering the general movement of the water masses, the circulation theory of Bjerknes having provided an additional means of attacking this problem. This necessitates exact data of the distribution of density of the water throughout the ocean, as do all hydrographic calculations. These values of density are obtained by calculation from the temperature and chloride content of the water at various depths and the greatest attainable accuracy is sought, since the final picture rests on very small differences. The years 1925–27 were spent by the *Meteor* in collecting such data at more than three hundred positions down to depths often exceeding three miles. Gear and instruments must stand up to their work under severe conditions, so it says much for their efficiency that the original plans were fully carried out.

The results of the expedition are now being published. Part I of vol. 4, "Ozeanographische Methoden und Instrumente" by Wüst, Böhnecke and Meyer, gives a very full account extending over 300 pages with numerous illustrations of the instruments—thermometers, water bottles, winch and current meters. A final chapter is devoted to the technique and organisation of chloride titrations carried out on board.

Two types of deep-sea reversing thermometers were used, one with an outer casing protecting it from the effect of pressure, the other not so protected. The latter acts as both thermometer and manometer. It was found in calibrating to have a constant pressure coefficient and was used to calculate the actual depths at which water samples and tempera-

* Deutsche Atlantische Expedition auf dem Forschungs—und Vermessungsschiff *Meteor*, 1925–1927. Wissenschaftliche Ergebnisse, herausgegeben im Auftrage der Notgemeinschaft der Deutschen Wissenschaft von Prof. Dr. Albert Defant. Band 4, Teil 1: Ozeanographische Methoden und Instrumente. Von Dr. Georg Wüst, Dr. Günther Böhnecke und Dr. Hans H. F. Meyer. Pp. xii+296+9 Tafeln. (Berlin und Leipzig: Walter de Gruyter und Co., 1932).

tures were taken. The following table shows the maximum and mean error of the depth as obtained by this means.

Actual Depth.	Maximum Error.	Mean Error.
100 metres	± 6 metres	± 3 metres
500 ,,	± 9 ,,	± 4 ,,
1000 ,,	±14 ,,	± 6 ,,
2000 ,,	±23 ,,	± 9 ,,
3000 ,,	±32 ,,	±12 ,,
5000 ,,	±49 ,,	±19 ,,

In taking soundings or samples from great depths, a material time is occupied by the lead and apparatus sinking to the desired depth. Meanwhile the ship may have drifted some distance, however skilfully manœuvred, and the line strayed from the ship making an angle to the vertical. During the expedition the angle of stray was observed and the effect of stray upon the actual depth reached investigated from the numerous data available.

A chapter is devoted to the protected type of reversing thermometer, in which an improvement was effected by using a thermometer tube of semi-circular section, the graduations being marked on the flat. The zero point of the thermometers in use was found at frequent intervals and diagrams are given showing the change in zero point with time.

There is no doubt that this volume will be of great assistance to anyone equipping an expedition for similar work.

Preservation of Timbers

IN *Forest Bulletin* No. 75 (Economy Series, 1931) of the Research Institute, Dehra Dun, India, Mr. F. J. Popham discusses the "Preservation of Indian Timbers—the Open Tank Process". This process consists essentially in submerging timber for a sufficient length of time in hot preservative and in keeping it submerged whilst the preservative is allowed to cool. A modification of this treatment, known as the butt treatment, is considered in Chap. ii of the *Bulletin*. In describing the method, the following considerations are dealt with by the author: (1) the vessel used for the treatment; (2) method of heating the preservative; (3) method of submerging the timber; (4) the preservative to be used; (5) the temperature of the preservative; (6) length of time to obtain desired results; (7) should the wood be seasoned before treatment; (8) varying treatment for different timbers; (9) cost of treatment.

It is recognised that although the open tank process of treating timber has many limitations, it also has much value, especially in India; and, it may be added, in many other parts of the British Empire, where there are many small users of timber who cannot afford a pressure plant. The capital outlay required for a full-sized pressure plant restricts the application of the pressure process considerably and leaves a wide field untouched. The open tank process, on the other hand, is cheap, and can have a wide application in regions and under conditions where the more expensive process is out of the question. The *Bulletin* is accompanied by five plates of line drawings illustrating the text descriptions. In an appendix a list of species of timbers not treatable in the heart wood by the open tank process is given.

Under the auspices of the Council for Scientific and Industrial Research, Commonwealth of Australia, Mr. J. E. Cummins has drawn up a small treatise entitled "The Preservative Treatment of Fence Posts (with Particular Reference to Western Australia)" (*Pamphlet* No. 24, Melbourne, 1932).

M. J. H. Boas, Chief of the Division of Forest Products, in a foreword, points to the inevitable experience of all countries which commence with what appears to be inexhaustible forest resources. Australia was fortunate in possessing timbers of remarkable durability under general conditions of service. These timbers were at one time plentiful; but as experience proved their value, the demand for them naturally increased. Supplies have in consequence become scarcer and prices are rising. Under these conditions the preservative treatment of less durable species becomes, not only economically possible, but also desirable. This is the seemingly inevitable cycle in all timber-producing countries. By the time experience has shown the true value of certain species for particular purposes, the demands of settlement and exploitation of the forests cause a serious depletion in the supply. Fortunately it is possible to treat many less durable species in such a way as to render them highly resistent to the attacks of fungi and white ants. On a farm there are generally supplies of fence post timbers which, when treated with preservatives, will have a length of life several times that of the untreated wood. The pamphlet sets out methods of treatment which have been shown to pay and can be practised by the farmer; the plant is cheap, can be easily and quickly erected, and the methods of treatment are simple. They are based on the treatment of 1,800 fence posts in West Australia.

Mr. Cummins points out that from the earliest days of farming in Western Australia the raspberry jam or jam post (*Acacia acuminata*) was recognised as the ideal timber for fencing posts and that fences constructed fifty to sixty years ago are still in a perfect condition. Jam, however, generally grows on good wheat land. In addition to an increase in farming areas in the jam country adjoining the Great Southern and Midland Railways, the so-called eastern wheat belt has been developed. This country carries little, if any, jam but several non-durable timbers. Jam posts were obtained, therefore, for the fences whenever possible, with the consequence that supplies are becoming scarcer and will become more so in future. With the increased price and reduced supply, the eastern wheat-belt farmer had to add a heavy freight to the initial cost of his fences.

As in the past in Australia, and elsewhere in the Empire, in clearing the land for the extension of agriculture, tea, coffee, rubber and so forth, the practice was, and is, in Australia, to destroy the greater part of the standing non-durable timber. The author's aim is to show that at very little extra cost fence posts could be cut from this material. Mr. Cummins deals with this question, as also that of material from thinnings from woods under proper management. He then discusses the main causes of timber deterioration and the reasons for differences in durability in different timbers. Preservatives, plant and estimated costs are considered, which merit the close attention of all interested in this question.

University and Educational Intelligence

CAMBRIDGE.—Prof. Walter Langdon Brown, regius professor of physic, and Prof. J. E. Lennard-Jones, Plummer professor of inorganic chemistry, have been elected fellows of Corpus Christi College.

WALES.—The Council of University College, Cardiff, at its meeting on Sept. 30 appointed Dr. W. F. Cassie as assistant lecturer and demonstrator in civil engineering in place of Mr. J. F. Barlow, who has resigned. The extension to the Metallurgy Department is now practically finished, and will be ready for occupation in the near future. Additional accommodation has been found necessary for the Zoology Department. This has been secured by extending the senior laboratory, and by building a new 'honours' laboratory.

SIR C. V. RAMAN, F.R.S., Palit professor of physics in the University of Calcutta, has been appointed director of the Indian Institute of Science, Bangalore, to succeed Dr. M. O. Forster, F.R.S., on his retirement in April next year.

SEVEN demonstrations of specimens in the Museum of the Royal College of Surgeons, Lincoln's Inn Fields, W.C.2, will be given by Sir Arthur Keith, Mr. Cecil P. G. Wakeley and Mr. R. Davies-Colley on Mondays and Fridays, beginning Oct. 17, at 5 P.M. The demonstrations are open to advanced students and medical practitioners.

As the result of a suggestion by the Association of Special Libraries and Information Bureaux, the School of Librarianship at University College, London, has instituted a course of training for special librarians. The course is open to graduates in faculties other than that of arts who desire to train for posts in special libraries, research departments, information bureaux, etc. It includes lectures on English composition, other languages, bibliography, cataloguing and indexing, literary history and book-selection, classification, history of science, palæography and archives, library economy and special library services. To meet the needs of the course, the regulations for the diploma in librarianship in the University have been modified. This course offers a splendid training for those who wish to enter the libraries of research departments, Government works, university and State libraries and other fields of activity, where scientific and technical knowledge, linguistic attainments and special training in the organisation of research are needed.

THE autumn programme of the twentieth annual series of Chadwick Public Lectures begins on Oct. 20 at 5.15 p.m., when Sir Humphry Rolleston will repeat in the theatre of the Royal United Service Institution, Whitehall, the Chadwick Lecture he delivered at the Paris Academy of Medicine last April, on "The Pioneers and Progress of Preventive Medicine". Sir William Collins, chairman of the Chadwick Trustees, will preside and at 5 o'clock will present to Mr. Alasdair Robertson the Chadwick Gold Medal and Prize for excellence in municipal engineering and hygiene, which is annually awarded to a student at University College, London, who has distinguished himself in the technique and sciences of engineering and sanitation. Other Chadwick Autumn Lectures are "Hygiene in the Far East—Progress under Difficulties" by Prof. Kielstra, of Leyden, who has had experience of these difficulties in the Dutch East Indies (Nov. 1); Sir Pendrill Varrier-Jones on "The Employment of Tuberculous Patients" (Nov. 15); and Dr. T. Carnwath, senior medical officer of the Ministry of Health, on "Public Health Administration" (Dec. 1). Discourses will also be delivered by Prof. S. D. Adshead at the Technical College, Bradford, on Nov. 21, on "Some Recent Developments in the Housing Problem" and by Dame Louise McIlroy at the Town Hall, Gateshead, on Nov. 25, on "Maternal and Infant Welfare". All Chadwick lectures are free and no tickets are required for admission. Further information about them may be obtained of the secretary, Mrs. Aubrey Richardson, at the offices of the Trust, 204 Abbey House, Westminster, S.W.1.

Calendar of Geographical Exploration

Oct. 11, 1579.—Sarmiento in the Strait of Magellan

Pedro Sarmiento de Gamboa sailed from Callao. Sarmiento had been many years in Peru, where he had become deeply versed in the ancient traditions of the Incas and had learnt of a voyage which they had made "towards the setting sun". Sarmiento then himself made this voyage from Peru and later, in 1567, discovered the Solomon Islands. His 1579 voyage was undertaken with the aim of intercepting Drake in the Strait of Magellan, it being thought that he would return that way. Sarmiento explored the channels in the Chonos Archipelago and carefully surveyed the Strait of Magellan. On his return to Spain he urged that the Strait should be fortified and colonies set up. In 1581 he sailed to carry out these suggestions, and after meeting many disasters, landed some of the colonists at a spot named San Felipe. He left for Chile, meaning to return with supplies; stormy weather intervened and he set out towards Spain but was taken prisoner by Raleigh. All but one of Sarmiento's colonists perished from famine, Cavendish inhumanly refusing to help those who were still alive when he arrived there in 1587.

Oct. 11, 1492.—Christopher Columbus

After a voyage in which he left Spain on Aug. 3, 1492, and the Canaries on Sept. 9, Columbus sighted land, probably Watling Island in the Bahama group, on this date. He reached Cuba on Oct. 28 and sailed to Haiti, from which island he returned to Spain in March, 1493. Academic controversies have recently raged round his name from the point of view of his aims and of his failure to grasp the significance of his discovery. But no criticism can affect the fact that he made the pioneer voyage across the Atlantic to the islands off the coast of Central America, and thence returned, thus opening up new possibilities in navigation and pointing the way for the rapid series of discoveries which followed his voyage. These subsequent discoveries so widened the outlook on world geography that it is difficult for modern writers to realise the limits of the geographical conceptions of the pre-Columban age. In a second voyage, in 1493, Columbus discovered Dominica and a number of adjacent islands and again examined Cuba, which he quite naturally, considering the fixed ideas of his time, thought to be part of the mainland of Asia. In 1498 he discovered Trinidad, noted the fresh water of the Orinoco River far out at sea and sighted the mainland of South America, near Paria. In a fourth voyage, Columbus in July

1503 sighted the coast of Honduras and followed it southward to the Gulf of Darien.

Oct. 13, 1884.—Sir Thomas Holdich's Surveys

The Russo-Afghan Boundary Commission assembled at Sarrakhs, the point where Russia, Persia and Afghanistan meet. Sir Thomas Holdich, with a very small staff, succeeded in carrying out a detailed and accurate survey from Kandahar to the Helmand, and thence through western Afghanistan to the Hindu Kush near Herat. He had already carried out some work on the north-west frontier of India in 1881–83. In 1889 he surveyed the Zhob valley and explored Makran. The Perso-Baluch Boundary Commission, and the Pamir Boundary Commission worked under his direction and his work and that of his surveyors covered large areas of previously unexplored country in Afghanistan, Baluchistan and the north-western regions of India. In 1902 Holdich directed the work of the boundary commission on the Chile-Argentine frontier in which Francis Moreno took part. Moreno had between 1873 and 1902 carried out a series of explorations in the Andes, Patagonia and Argentina which were of the first importance.

Oct. 14, 1872.—N. M. Przhevalsky's Explorations in Asia

The famous Russian explorer Przhevalsky reached Kuku Nor from Kiakhta, following much the same route as that of the Abbé Huc in 1843–46. In this 1870–73 journey Przhevalsky, with only three companions, crossed the Gobi desert, reached Peking, explored the Ordos, the Ala-Shan and the upper course of the Yangtze Kiang, and got so far as the Di-Chu River in Tibet. In 1877 he re-discovered Lop Nor, in 1879–80 he penetrated the Tsai-Dam and followed the valley of the Tibetan river, Kara Su, approaching within 170 miles of Lhasa. Altogether he made five expeditions into these regions, in addition to an earlier exploration, carried out single-handed, in the Ussuri region, in 1867–69. He died at Karakol on Lake Issyk Kul when he was attempting a further journey to Lhasa. His interests were wide and in addition to their geographical importance, his journeys resulted in valuable collections of plants and animals and of ethnographic data. He discovered the wild camel and the early type of horse now known by his name.

Oct. 15, 1819.—South Shetland Islands

William Smith in the *Williams* sighted the South Shetland Islands and claimed them for Britain. Smith was a trader and had on a previous voyage seen the islands, but had not ventured near them because he feared to lose his cargo. The *Williams* was in the following year chartered by the British naval commander of the Pacific station for a voyage of discovery. Edward Bransfield was put in charge and explored and charted the group between Jan. 16 and March 21, 1820.

Societies and Academies

PARIS

Academy of Sciences, Aug. 17 (vol. 195, pp. 429–448).—**Charles Achard and Ho-dac-an**: Some observations on the flocculation of suspensions of myxoprotein by electrolytes. The existence of two zones in the flocculation curve of myxoprotein by the two electrolytes studied, $AlCl_3$ and $ThCl_4$, leads provisionally to two hypotheses: myxoprotein contains two different substances or there is a change of sign in the protein.—**E. Bataillon and P. Tcherniakofsky**: The sterility of the male hybrids resulting from crossing *Molge marmorata* and *Molge cristata*.—**R. Risser**: The proper dispersion with *n* errors in the case where each of the component errors is ruled by a simple law. An attempt at an analytical representation.—**Jacques Devisme**: Certain families of polynomials.—**D. Iwanenko**: The constitution of the atomic nuclei.—**A. Portevin and P. Bastien**: Contribution to the study of the ternary system magnesium-aluminium-copper.—**Li Shi Lin**: Study of some ottrelite schists from China.—**Henry Germain**: Some fresh-water diatoms living in mucous tubes.

Aug. 22 (vol. 195, pp. 449–472).—**E. Bataillon and Tchou Su**: Crossings (second generation) between a female hybrid and males of two parental types.—**Paul Mentré and O. Rozet**: Certain tetrahedral surfaces.—**Georges Giraud**: An extension of the theory of the Fredholm integral equations, with application.—**Gr. C. Moisil**: The integration of matrices.—**A. Aleyrac**: Remarks on the support of a body by (wing) beats.—**J. Solomon**: The theory of Einstein and Mayer and the equations of Dirac.—**G. Bruhat and P. Chatelain**: The photoelectric measurement of the rotatory dispersion of some sugars in the beginning of the ultra-violet. Measurements are given for wavelengths ranging from 5,461 to 3,021: the formula of Lowry and Richards was found to hold over this range.—**Michel Polonovski and Albert Lespagnol**: The constitution of allolactose. This sugar is shown to be an isomer of lactose.—**D. Ivanoff and T. Roustcheff**: The alcoholysis of esters by mixed organomagnesium alcoholates and phenolates. A study of the reaction $R.CO_2R_1 + R'OMgX = R.CO_2R' + R_1OMgX$. In the eleven cases examined the yields varied from 0 to 69 per cent.—**F. Blanchet and L. Bethoux**: The influence of the geological nature of the soil and of the mineralisation of drinking water on the frequency of cancer in man.

Aug. 29 (vol. 195, pp. 473–504).—**C. Camichel, F. Beau and L. Escande**: The similitude of short hydraulic systems: experiments on the dock of the port of Havre.—**G. Tzitzéica**: Conformal representation.—**Torsten Carleman**: The characteristics of the torus.—**Georges Bouligand**: Various ideas concerning infinitesimals.—**Alexandre Ghika**: The development in series of uniform monogene functions.—**Giulio Krall**: The limiting state resulting from the tides for the movement of a planetary system.—**P. Vaillant**: A device susceptible of increasing the precision of optical spectrophotometric measurements.—**J. Prat**: The combinations of arsinic acids and hydrochloric acid.—**Vale Vouk**: The biology of *Codium Bursa*.—**A. N. J. Heyn**: The method of determining the plasticity of cellular membranes.—**G. Viaud**: The phototropism of *Daphnia pulex*: the rôle of memory in phototropism.—**G. Champetier**: A method for determining the composition of addition compounds of cellulose.—**Jean Roche**: The muscle hæmoglobins. Muscle and blood hæmoglobins are representatives of the same type of pigment the spectra of which are determined by the same laws.

CRACOW

Polish Academy of Arts and Letters, July 4.—**Stan. Ziemecki**: The Raman spectra of naphthalene derivatives. The spectra of five naphthalene derivatives have been examined. The line 1376 is always

present: it is very intense and evidently characterises the naphthalene nucleus. These results are analogous with those obtained with benzene. Certain well defined types of molecular structure can be established by the Raman spectrum.—**L. Marchlewski** and **Wl. Gabryelski**: The absorption of the ultra-violet rays by certain organic substances (27). A description of the absorption spectra of the polysaccharides.—**L. Marchlewski** and **T. Surzycki**: The absorption of the ultra-violet rays by certain organic substances. (28)—**K. Dziewonski, J. Moszew, Mlle. G. Dortheimer**, and **W. Rozycki**: A new method of synthesis of compounds derived from quinoline.—**T. Domanski** and **J. Suszko**: α-Quinidine. By treating quinidine with strong hydrochloric acid and submitting the product to alcoholic alkali solution, a new alkaloid, α-isoquinidine, is obtained.—**St. Kreutz**: The luminescence of minerals in relation with the places at which they are found and with the conditions of their formation. The differences between the luminescence of minerals of different places of origin is marked, and may be of service in determining the country of origin.—**A. Malicki**: Changes in relief of the terrestrial globe.—**Mlle. A. Cehak**: The quantitative determination of the deformations of the longitudinal profiles of the water courses of Pokucie.—**H. Bolkot**: The hypsographic curves of North America and of South America.—**J. Wiertelak**: The influence of white rot on the chemical composition of wood. White rot causes considerable losses of lignin, together with a slow decomposition of the carbohydrates. The loss of weight is marked, amounting in one case to 15 per cent.—**E. Pischinger**: The phosphorus compounds of plants (7). The solubility of the phosphorus compounds of hemp seed.—**L. W. Wisniewski**: *Cyathocephalus truncatus*, its development, morphology and biology.—**L. W. Wisniewski**: Two new progenetic trematodes of the Balkan Gammarideæ.—**Mlle. J. Ackermann**: The innervation of the skin of the frog (*Rana esculenta*).—**Mlle. J. Janiszewska**: Studies on *Aphidius*, a hymenopteran parasitic on the aphis *Hyalopterus pruni*.—**Mme. N. Natanson-Grodzinska**: The structure of the tegument of the aquatic larva *Cataclysta lemnata* and its function in respiration.—**Z. Grodzinski**: Observations on the lymphatic system of *Myxine glutinosa*.—**L. Sedlaczek-Komorowski**: Man of the age of the caliciform vases in Poland.

VIENNA

Academy of Sciences, June 16.—**Leonore Brecher**: Butterflies (*Vanessa Jo.* L.) direct from caterpillars. Of ten of these caterpillars, eight formed chrysalides and butterflies in the usual way, whilst the other two kept under the same bell-jar gave rise directly to stunted butterflies.—**Karl Huttrer**: Means for the analysis of the formation of butterfly markings. From observations made, it is concluded that neither the assumption of sensitive states nor the retardation theory suffices to explain the action of external factors on the formation of these markings.—**Erich Murr**: Direct dependence of the tail-length of the ferret (*Putorius furo* L.) on the temperature. The increased rectal temperature observed with pregnant ferrets kept at a temperature higher than usual is accompanied by increase in the length of the tails of the offspring.—**Hans Przibram**: (1) Regeneration of feelers and legs with phasmids (VIII): Attempts to find conditions for orthomorphic, heteromorphic or defective growth after removal of the feelers of *Dixippus morosus* Br. et Redt.—(2) Growth of appendices in allied locusts (*Sphodromantis, Mantis*).—(3) The 'lower' males of the rhinoceros beetle, *Oryctes nasicornis* L. as heat-forms.—**Toshihiko Yamanôuti**: Coprometry for the measurement of the growth of Orthoptera.—**Kasimir Graff**: The photometric system of the Holetschek nebula catalogue.—**Fritz Kerner-Marilaun**: Anisothermy in spring horizons and its geological significance.—**K. W. F. Kohlrausch, H. Kopper** and **R. Seka**: The Raman spectrum of organic substances (isomeric paraffin derivatives, ii). Secondary butyl alcohol, isobutyric acid, tertiary anyl iodide, and nine isobutyl derivatives, $(CH_3)_2 . CH . CH_2X$ ($X = CH_3$, OH, NH_2, SH, Cl, Br, I, NO_2 and NO_3), have been examined. The results show that, in a polyatomic molecule, RX, a physical meaning is attached to the valency frequency $C-X$, if the substituent X differs markedly in weight from the other groups—CH_3, CH_2—of the substituted paraffin.—**A. Dadieu, K. W. F. Kohlrausch**, and **A. Pongratz**: The Raman spectrum of organic substances (isomeric paraffin derivatives, iii). The results furnished by isoamyl and secondary butyl derivatives, in conjunction with those previously obtained, serve for the determination of the frequencies of the valency vibration of the carbon-halogen linking. Duplication of these valency frequencies occurs only and always if the molecule is able to assume different space-forms owing to free rotation. The frequency is related to the number of hydrogen atoms attached to the carbon atom of the carbon-halogen linking.—**Gustav Beer**: The convexibility of regular curves.—**Erich Haberfelner**: The history of the development of the monograptids.

WASHINGTON, D.C.

National Academy of Sciences (*Proc.*, vol. 18, 409–480, No. 6, June 15).—**P. Debye** and **F. W. Sears**: On the scattering of light by supersonic waves. (See NATURE, vol. 130, 281, Aug. 20, 1932).—**Linus Pauling** and **Don M. Yost**: The additivity of the energies of normal covalent bonds. A normal covalent bond is defined as that between two unlike atoms of the same degree of negativity, and it is postulated that the energies of such bonds are additive. Experimental data of other workers is in fair agreement with this hypothesis.—**Marston Taylor Bogert** and **Torsten Hasselström**: Investigations in the retene field (2). Alpha-retene carboxylic acid and some of its derivatives.—**F. E. Lloyd** and **T. Cunliffe Barnes**: Changes in the cells of *Spirogyra* associated with the presence of water polymers. Ice water from ice formed over running water and also newly condensed steam were used in series of experiments on *Spirogyra nitida*, with and without the addition of nutritive salts in the form of Knopf's solution. Ice water, which contains much trihydrol, promotes reproductive activity at room temperature, as well as at 10° C. as reported previously. In the presence of Knopf's solutions, the filaments became tightly coiled in addition, indicating a high state of vigour.—**Edgar Anderson**: Character recombination in *Drosophila*. Regarding recombination of genes as a recombination of 'strings of beads' the lengths of which depend on the lengths of the cross-over segments, the effect of length and number of such 'strings' should be morphologically demonstrable.—**M. Demerec**: Effect of temperature on the rate of change of the unstable miniature-3 gamma gene

of *Drosophila virilis*. Observations on flies reared at 20°, 25° and 30° respectively suggest that at the higher temperatures, the character is more stable; the result is due, however, to the decreased size and crumpled wings produced. The frequency of change is independent of sex although the female carries approximately twice as many 'miniature' genes as the male.—C. R. Burnham: An interchange in maize giving low sterility and chain configurations.—R. A. Brink and D. C. Cooper: (1) A strain of maize homozygous for segmental interchanges involving both ends of the *P-br* chromosome.—(2) Chromosome rings in maize and *Œnothera*. The hypothesis of simple segmental interchange, although giving a satisfactory explanation of the chromosome attachments in *Œnothera*, does not account for those in maize. Other mechanisms are suggested and discussed.—E. B. Fred: The stability of physiological characters of bacteria. Cultures of nitrogen-fixing bacteria, lactic acid bacteria and tubercle bacteria kept in the laboratory for various periods up to twenty years and tested from time to time have shown no appreciable change in character.—Harry Merrill Gehman: Concerning sequences of homeomorphisms.—Edward V. Huntington: An improved equal-frequency map of the normal correlation surface, using circles instead of ellipses. Concentric circles and a family of equally spaced radial lines are drawn, forming a 'cobweb' map which divides the plane into 'townships of equal frequency'. From this map it is possible to make a direct comparison between the observed distribution of dots and the theoretical distribution in the corresponding normal case.—A. W. Tucker: Modular homology characters.—G. A. Miller: Orders for which a given number of groups exist.—Edward Kasner: Geometry of the heat equation: first paper. Heat curves are defined as the loci of constant temperature throughout a given flow of heat.

Forthcoming Events

TUESDAY, OCT. 11

ILLUMINATING ENGINEERING SOCIETY.—Lieut.-Commander H. T. Harrison (Presidential Address) at the Lighting Service Bureau, 15 Savoy Street, Strand, W.C.2, at 7 P.M.

INSTITUTE OF EDUCATION, LONDON.—Prof. C. H. Becker: "Educational Problems in the Far and Near East", at 5.30 P.M. (succeeding lectures on Oct. 12 and 13).

KING'S COLLEGE, LONDON.—Dr. J. W. Pickering: "Blood Plasma and Platelets", at 5 P.M. (succeeding lectures on Oct. 18, 25, and Nov. 1).

THURSDAY, OCT. 13

KING'S COLLEGE, LONDON.—Dr. W. Robson: "The Metabolism of Carbohydrates, Fats and Proteins", at 5 P.M. (succeeding lectures on Oct. 20, 27 and Nov. 3).

FRIDAY, OCT. 14

LONDON HOSPITAL MEDICAL COLLEGE.—Mr. S. P. Bedson: "Some Recent Work on Filterable Viruses and its Significance", at 5 P.M.

Post Office Reform

WE do not know whether it was mere coincidence or good stage-management that Lord Wolmer's book on "Post Office Reform" (Ivor Nicholson and Watson, Ltd., 6*s*. net) was published a week before the report of the Committee of Enquiry on the Post Office (Cmd. 4149. H.M. Stationery Office, 9*d*. net). However this may be, no study of the findings of that Committee can avoid reference to Lord Wolmer's campaign since he ceased to hold office as Assistant Postmaster General, for it was his persistence, supported ultimately by more than three hundred members of Parliament of all parties, which led directly to the appointment, by the present Government, of Lord Bridgeman and his colleagues, Sir John Cadman and Lord Plender, as a Committee "to enquire and report as to whether any changes in the constitution, status or system of organisation of the Post Office would be in the public interest".

Criticism of governmental administration is no modern diversion, and the Post Office, like other great departments of State, has not escaped the baiting to which 'bureaucracy' is always liable to be subject from those who as a matter of principle abhor State intervention, particularly in the sphere of commerce. Nevertheless, as a result of the reforms associated with the name of Rowland Hill, the attitude of the public towards the Post Office, personified in that popular character the postman, has been not unfriendly. The speed and accuracy of its letter-carrying activities and the extent of at any rate the pre-War facilities as regards deliveries and collections indeed left little to be desired.

Serious criticism of the Post Office only began to arise after the Office, in 1912, became solely responsible for the administration of telephone services, and it is the relative backwardness of telephone development in Great Britain in comparison with other countries, coupled with a certain administrative inelasticity, that has supplied the real driving force of Lord Wolmer's campaign. On one hand, as Lord Wolmer insists, it is a fact that the number of telephones per thousand of population is lower in Great Britain than in most other countries; that this feature is also apparent if large cities at home and abroad are compared; and that such telephones as are installed are less used than those in other countries. On the other hand, it is equally an undoubted fact, to which the Bridgeman Committee pays handsome

testimony, that the Post Office engineers have led the way in technical development in telephony and, we may add, in electrical communications generally. Yet with this tremendous advantage of an able and alert, if underpaid, technical staff, foremost in promoting the development of this highly technical industry, there has been, rightly or wrongly, widespread public dissatisfaction with the telephone service. If such dissatisfaction had not existed, it would have been impossible for Lord Wolmer's campaign to gather the necessary momentum to lead the Government to appoint the Bridgeman Committee of Enquiry.

The report of the Committee summarises as follows "the rather generalised charges" that have been made :—

(1) An absence of the spirit of public service, among certain sections of the staff—an attitude of indifference instead of a desire to help the public.
(2) A lack of initiative and an absence of elasticity and imagination in adjusting service to meet the reasonable variations in the public demand; prompt action is thought to be hampered by 'red tape' and dilatory procedure.
(3) In general an absence of the commercial outlook necessary for the efficient conduct of what is, at any rate to a large extent, a business concern.
(4) A failure in regard to the telephone and telegraph services which are of a highly technical character, to give proper scope to the engineer, whereby technical progress is impeded.

This summary may to some extent be taken as reflective of the criticisms of Lord Wolmer, who argues that the telephone and telegraph services have not been administered on commercial lines because they have been administered by a Government department organised on the traditional Whitehall basis, with all that such organisation necessarily involves in rigidity of administration, owing to day-to-day accountability to Parliament in regard to the minutest details; inability to take normal commercial risks as a result of financial control by the Treasury; and above all in the arrangement, copied from Whitehall, under which all sub-departments come to a narrow bottleneck at the Secretary of the Post Office, so rendering promptness of decision impossible.

In the controversies generated by Lord Wolmer's campaign, the serious questions of organisation involved have tended to become obscured by political factors. The fundamental issue has been represented to the public as being primarily one of the respective merits of public and private enterprise; and to overcome the weaknesses of Post Office administration, reformers have offered us a choice between the transfer of the Post Office communications services either to a public board on the model of, say, the Port of London Authority, or to a public utility company analogous to the Imperial and International Communications Company Limited, which is now responsible for all international wireless telegraph services originating in Great Britain. Unfortunately, the form which the public controversy has taken has caused certain essential elements of the problem to be overlooked, especially the obvious but all-important fact that, although for historical reasons the postal, telegraph and telephone services have become closely interlocked, the industrial structure of the Post Office, as regards electrical communications, is very largely, indeed almost entirely, the fashioning of scientific discovery and invention. The telegraph and telephone services are dependent, to a much greater degree than are the mail-carrying services, upon research and technical progress. No change of ownership or control which fails to take account of this fundamental fact is likely to achieve the desired results.

These considerations are by no means novel, for they were in the minds of that somewhat unpromising body the Select Committee on the Telephone Service, appointed so long ago as 1922 "to inquire into the organisation and administration of the telephone service and the method of making charges". That Committee emphasised that telephone business is essentially commercial and must be *administered on commercial lines*. It pointed out that the carriage of letters has always been upheld as the main foundation on which Post Office management rests, and when the telephone and telegraph undertakings were in turn transferred to the Post Office, "it seems to have been decided to patch them into the existing organisation rather than to alter the organisation to suit the extended conditions". The Committee recommended, therefore, the separation of the telephone and telegraph services from the mails. It also pointed out that "the Secretary's Department at the General Post Office, which really controls it, has neither special business training other than that of the ordinary Civil Service, nor special expert and technical qualifications", and it hinted at the desirability of the establishment of an administrative board

for the control of the segregated telephone and telegraph services. Finally, the Committee insisted that greater weight should be given to technical knowledge both in settling policy and in ordinary routine.

The Bridgeman Committee again and again throughout its report pays tribute to the zeal and ability with which the Post Office staffs carry out their duties. Yet the Committee is constrained to state that the criticisms of the telephone service "are not devoid of some substance", and that it believes that "there is room for improvement", but that "such improvement can only come from a removal of certain fundamental impediments to efficiency". These fundamental impediments are considered to be the relationship in which the Post Office stands as a revenue department to the Exchequer, and the internal organisation of the Post Office. The Committee, however, rejects the transference of all Post Office communication services to an independent authority of the public utility company or statutory corporation type, for it considers that "the public have a right to the influence which Parliamentary discussion and control alone can give". The proposal for the transference of electrical communications to an independent authority is also rejected. It is admitted that there might be advantages in this course if it were a question of inaugurating for the first time in Great Britain a new system of communications, but the Committee makes a point of considerable importance which, it must be admitted, has the force of expediency. Under present conditions, in all but the largest offices, the counter staff now deal indiscriminately with all kinds of business, and in all the smaller towns the sorting and telegraph operating staffs are combined to good effect, since the 'peak' hours of postal work are usually outside those of telegraph business. Separation, in the view of the Committee, "would entail large additional expense and would result in two separate organisations, neither of which would be carrying a full load."

Limitations of space prevent us from dealing with the first of the above-mentioned impediments to efficiency. We need only say that, in the view of the Committee, "In the present state of the National finances it would be impracticable to suggest any other principle than that the Exchequer should retain out of the net revenue collected by the Post Office a sum approximating to the amount which it is at present receiving."

As regards the second fundamental "impediment to efficiency", namely, the system of administrative control at the Post Office itself, the Committee is more drastic. It considers, in the first place, that there is far too much centralisation of staff management at headquarters and too little freedom left to the local officer in the provinces. It believes that much of the dissatisfaction with the telephone system is due to the general diffusion of responsibility and absence of co-ordination between those concerned with the various elements involved in the provision and conduct of the service. There is, the Committee says, "no one authority who can deal with complaints or ensure that orders are promptly and satisfactorily executed". The District Manager, who is, broadly speaking, responsible for the telephone service in his area, has no jurisdiction over the engineering and little disciplinary control over the operating staff. The Committee states that the District Manager is also handicapped by the restriction of his executive authority and is subjected in such matters as publicity, canvassing, etc., to rigid control by headquarters on matters of outlay and method, which tends to repress zeal and initiative as well as to waste time and money.

The Committee proceeds to remark that the Post Office Secretariat "has come to acquire a status out of proportion to that of other Post Office departments"; no executive department of the Post Office can give an instruction to another department, nor can it through its own officers do anything for which it has not Secretariat authority. The present position of the Secretariat, it is stated, "contravenes the fundamental principle of organisation, namely, the distinction between policy and practice, between the administrative and the executive functions". The Committee considers that the neglect of this important distinction is one of the main weaknesses of the existing Post Office organisation, and it arrives at the same conclusion as the Select Committee of 1922 that the Secretariat, as at present constituted, is unsuited by training and experience for the duty of conducting the daily business of the Post Office services, which function it undertakes in addition to the framing and formulation of policy. It is noted too that, owing to the "autocratic isolation of the Secretariat", the Engineering and Accountant General's Departments are prevented from taking an adequate part in the general scheme of control, and although the Committee considers there is no evidence that the engineer is unduly

hampered, it believes that engineering experience is insufficiently brought into the consideration and formulation of general policy.

Such serious defects demand radical treatment, and the Committee recommends that the control of all Post Office business shall be taken out of the hands of the Secretariat and effected through the medium of a functional Board, presided over by the Postmaster General. In addition to the Assistant Postmaster General the Board should, it is suggested, comprise four or five members of the Post Office staff representing such functions as general operating and supply, engineering and research, finance, and personnel. In the absence of the Postmaster General the Board would be presided over by the senior permanent member, who would carry some such title as 'Director General', and whose duty it would be to ensure that Board decisions were made effective, that continuity and unity of policy were maintained, and that the general machine of administration worked smoothly and effectively. The duties of the Board would, so far as possible, be restricted to the consideration and formulation of policy, leaving to the heads of the district organisation the duty of translating into effect the policy prescribed by the headquarters board. In the provinces it is recommended that the local administration should be controlled by regional directors who would constitute the co-ordinating authority for their respective regions and whose organisation would in effect be a reproduction in miniature of the headquarters board. It is in the application of this recommendation that controversy is not unlikely to arise, for the engineers in each district, hitherto autonomous, would thus come under the local control of a regional director, who might or might not be a 'telephone' man.

Other vital recommendations are that the existing division between the Secretariat and the rest of the staff should be removed and fluidity of interchange of staff between headquarters and the provinces secured. The Committee proceeds to make the long-awaited recommendation from a public inquiry: "As regards access to administrative posts, we consider that there should be no bar to a technical officer holding such posts, provided he has shown himself to possess administrative ability." With regard to the problem of the technical expert, the Committee considers it essential in an organisation such as the Post Office, which depends so much upon scientific discoveries and developments and their practical applications, to bring engineering and research into more intimate touch with the general problems of administration.

In its appreciation of the fundamental weakness of present-day Civil Service administration the Committee has rendered an important public service. That the higher administrative posts in Government departments are commonly held by individuals of exceptional ability cannot be challenged, but a system under which almost autocratic powers of control and the monopoly of the formulation of policy are solely vested in individuals who may have no knowledge of or sympathy with scientific and technical developments can only be described as a national menace; for what the Bridgeman Committee has discovered in the Post Office can equally be said *mutatis mutandis* of most of the larger departments of State. The remedy proposed—the introduction of the Board system, under which departmental chiefs, both technical and non-technical, would be given a full opportunity of taking their proper share in the formation of policy—is one we have consistently advocated. The Committee's recognition of the importance of the expert and of the folly of debarring him irrespective of his administrative capacity from positions of control is of first importance. The divorce between the administrator and the technologist, the failure to achieve anything like a complete synthesis of the administrative and technical sides, is not peculiar to the Post Office in particular or to government departments in general. It characterises far too many business and industrial organisations.

In a paper read last year during the centenary meeting in London of the British Association for the Advancement of Science, Major L. Urwick, the director of the International Management Institute, Geneva, pointed out that throughout the century of the life of the British Association, despite the immense services which the inductive sciences are rendering to industry, it apparently has never occurred either to industrialists or to men of science that these services are other than contributory or ancillary. The Bridgeman Committee is the first public inquiry committee to give full recognition to the scientific expert in the Civil Service scheme of things. What it proposes amounts in sum to this, that the scientific expert is to be brought into the industrial family on level terms with the administrative expert and the financial expert and to have his due say as well in the formulation of policy as in the control

and execution of the routine operations. There is no suggestion that the business of the Post Office should be turned over entirely to the technologists. Viscount Bridgeman and his colleagues say sensibly: "Generally speaking we think it to be true that the specialist in any walk of life tends to remain a specialist; but there are, of course, well-known exceptions to the contrary, and we consider that where a member of the technical staff has shown that he possesses administrative talent he should be eligible for other appointments." No champion of the scientific worker in industry need ask for more than this or should be satisfied with less. The recommendation of the Bridgeman Committee, "to bring engineering and research into more intimate touch with the general problems of administration" is to be welcomed, not only for the beneficial effects which, if it is adopted, it is likely to have on the development of the Post Office, but also, and perhaps especially, for the stimulus it may give to the wider movement to bring about a closer fusion of science and industry and to get the scientific worker fully adopted into the industrial family.

Anthropology in Nigeria

Tribal Studies in Northern Nigeria. By C. K. Meek. Vol. 2. Pp. viii + 633 + 48 plates. (London: Kegan Paul and Co., Ltd., 1931.) 25*s.* net.

IN this work Mr. Meek apparently concludes his valuable notes on some of the smaller and lesser known peoples of Northern Nigeria—more than a score in all. As in the first volume (see NATURE, vol. 128, p. 285; 1931) chief attention has been paid to linguistics and social organisation and little to religion, which in the main consists of animism and ancestor worship. Each tribe is dealt with separately, and no attempt is made to give a general description of any particular custom or belief—doubtless the wisest course to pursue until more information has been collected.

One of the immediate practical advantages to be gained from these studies is that it should now be possible to group these peoples more scientifically; at present the Katab, for example, are not only divided by provincial boundaries, but also some of them are directly administered by British officers, while others are under Fulani emirs. One of the chief defects of indirect rule, as practised in Northern Nigeria, lies in the fact that so many pagan tribes have no native courts of their own but are subject to the judicial administration of Mohammedan alkalis.

Most of the peoples under consideration are of ancient semi-Bantu origin and possess interesting features in the way of totemism, exogamy and mother-right organisation. As is usual in Nigeria, totemism is mixed up with metamorphosis and is now fast breaking down. There is a certain amount of evidence for the belief that clan exogamy—at any rate in this region—arose from a desire to avoid local conflicts, and has nothing to do with consanguinity or the hypothetical unattractiveness of the woman whom you see every day; among the Piti, for example, intermarriage is most usual between those 'wards' which are nearest to one another. Fundamentally, no man may marry a woman of his own clan but, as the sense of kinship with the parent community dwindles, the exogamic taboos become confined to the new group.

There are examples of all stages of development, from the mother-right Longuda to the Kanakuru, who are mainly patrilineal though matrilineal in totemistic affairs, and the wholly patrilineal Bornuese tribes. Marriage is often matrilocal, and the children may be handed over to the mother's relatives, though occasionally to those of the father.

Until lately, marriage by capture was quite usual and traces of the custom are found in most tribes. One of the commonest methods of obtaining a wife is that of elopement with a married woman from another group or clan—a transaction previously regularised by payments to her family. This practice is apparently recommended, since it gives each party the opportunity of finding the one who suits him, or her, best; the original marriage is generally arranged at a very early age, sometimes even before the girl's birth. Children begotten of the second husband, as a rule, belong to him, but he cannot claim the return of his dowry should the woman leave him in turn, while the first husband practically never does so, as he always lives in the hope of her coming back to him.

Indeed, the position of women here, as in so large a part of West Africa, is highly enviable. The man is always anxious to gain, or keep, the services of at least one wife to cook for him; among the Gabin, where the women make the beer, they do not hesitate to dictate as to the friends who are allowed to partake of this, and even to forbid their husbands to attend a neighbouring celebration, if they consider that these would be better employed at home. The husband must continue to pay court not only to his wife,

but also to her maternal relatives, else they may transfer her to another suitor. The more attractive she is—and it is of interest to note that among the Kanakuru slimness is considered a beauty—the greater efforts must be made by him to counterbalance those of his would-be rivals. In fact, many husbands may be said to spend most of their time in endeavouring to retain their wives or in working out plans to obtain the wife of some one else.

The birth of a child before the mother's cicatrisation ceremonies have been carried out among the Yungur and Kona Jukun—or, with the Hona and Gabin, before the ordained time—is a serious offence; the consequences are usually avoided by abortion. A Katab woman marks each month of pregnancy by putting a circular dot of red earth on her thigh, while the husband keeps his own private tally in case his wife runs off before giving birth to the child.

Mr. Meek's volume is profusely illustrated, but the index would be of much more use if it were fuller; at present, if it is desired to look up, say, a certain fact about the Fulani, it may be necessary to go through the whole fifty-three references under this heading.

P. AMAURY TALBOT.

Poesy in Combustion

A History of Fire and Flame. By Oliver C. de C. Ellis. Published for the Poetry Lovers' Fellowship with the International Fellowship of Literature. Pp. xxiv + 440 + 20 plates. (London: Simpkin Marshall, Ltd., 1932.) 15*s*. net.

A PROBLEM that the alchemists found extremely difficult to solve was the preparation of an amalgam of iron. Dr. Ellis has attempted an analogous task, namely, the fusion into a homogeneous unity of the cold and hard scientific facts of the history of fire with the æsthetic appeal of fire and flame to his poetical emotions. The result is a book *sui generis*, which will be variously estimated according to the point of view from which it is surveyed. It is scarcely within the province of the present reviewer, and still less within his capacity, to appraise its merits as a work of art, though Dr. Ellis's mellifluous prose and well-developed sense of style must afford pleasure even to the most Philistine of his readers. The book is, however, by no means easy to understand, partly because the author's fancy leads him to stray down every attractive by-path, and partly because his wealth of quotation and allusion is apt to prove bewildering to anyone less familiar than himself with the original literature.

While every topic relevant to fire and flame—from the unicorn and the phœnix to the history of lucifer matches—is fitted neatly into the pattern, the pattern still remains somewhat kaleidoscopic, and the main arguments consequently have to be discovered by a process of induction. It is only just to add that the process is well worth undertaking, for Dr. Ellis's ideas are often highly original and frankly opposed to many opinions now generally accepted. Indeed, judged as a scientific history of certain fundamental chemical discoveries, the book demands serious attention.

One of the principal theses is that "the prime secret of the alchemists was oxygen". It is, of course, undeniable that oxygen must have been liberated on innumerable occasions during the progress of alchemical operations; but the same statement is equally true of hydrogen, hydrogen sulphide, hydrogen chloride, carbon dioxide, carbon monoxide, ammonia, and nitrogen peroxide, so that one turns with interest to see how the thesis is supported and what value is to be assigned to the evidence adduced. Such an examination makes it only too clear that Dr. Ellis is rather easily satisfied. He first assumes that the alchemists were able to collect oxygen by heating 'nitre'. It is possible—indeed, it is practically certain—that the early alchemists used potassium nitrate, but for the most part 'nitre' or 'nitrum' was applied to naturally occurring sodium carbonate, and a sharp distinction between the latter and the substance we now call nitre was not drawn earlier than the thirteenth century.

When Dr. Ellis says that "the earliest historians, geographers, and technicians speak of vast alluvial deposits" of nitre, that is, potassium nitrate, he is misinterpreting the sense of the Latin *nitrum*, which here signifies *natron*. Again, he quotes Virgil: "I have seen many sowers artificially prepare their seeds and steep them first in saltpetre and black lees of oil". He does not give the reference, but presumably the passage is that in the "Georgics", i. 193-196:

semina vidi equidem multos medicare serentes,
et nitro prius et nigra perfundere amurga,
grandior ut fetus siliquis fallacibus esset,
et, quamvis igni exiguo, properata maderent.

There is nothing in this description to suggest that by *nitrum* Virgil meant saltpetre; on the other hand, natron would fit the context, since it appears to have been believed by the Romans that plants

grown from seeds treated in this way would be softer and greener on cooking. Pliny ("Historia Naturalis", xxxi. 115) says that *nitrum* was used in cooking vegetables to give them a greener colour: such *nitrum* could scarcely have been anything but soda. Further, Dr. Ellis says that "nitre was a familiar weapon of the medieval chemist, in whose mind it was associated with fire as naturally as air was". What limits he sets to the Middle Ages he does not say, but in any event such a sweeping generalisation needs a good deal more documentary evidence than he is able to bring forward.

There are several other points in which Dr. Ellis's accuracy is far from unimpeachable. Thus he complains that there is no English translation of Mayow's "Five Treatises" (which he describes as "an amazing pack of nonsense"), though an excellent translation was published in the Alembic Club Reprints (No. 17) in 1907; he attributes the celebrated generator to Kipps instead of to P. J. Kipp (1808–64); he equates the alchemical 'tinctures' to 'slags'; and he says that the phlogistians conceived phlogiston as a palpable, substantial chemical 'sulphur'. Moreover, the passage from Paracelsus that Dr. Ellis takes to be a description of the preparation of phosphorus from urine is capable of interpretation in many other and much more probable ways; while the quotation from the "Demonolatry" of Nicholas Rémy does not carry conviction—at least to the reviewer—that phosphorus was known in 1588. Finally, Dr. Ellis's tentative identification of Eirenæus Philalethes (properly Philaletha) with Boyle has little to recommend it, in view of the fact that the only definite knowledge we have of this alchemical writer is that he was twenty-three years of age in 1645, when Boyle was eighteen.

In spite, however, of the too frequent carelessness shown in verifying references, and in spite of Dr. Ellis's tendency to credit the alchemists with more knowledge than they can be proved to have had, the "History of Fire and Flame" is a fascinating, informative, and beautiful book. No one who turns its pages will fail to catch some of Dr. Ellis's enthusiasm for his subject, or to experience (even if vicariously) some of his æsthetic emotion. There are passages of great poetic charm, and, equally, passages of keen historical insight, while flashes of dry humour sparkle in unexpected places and add a lively flavour to the whole. Nor, though his facts are not always above suspicion, is Dr. Ellis's critical judgment lacking. As Watson once wrote of a book of Nollet's, "he has traced the origin of several happy inventions, and has exhibited the real authors of them. He has given, as he imagines, additional value to several experiments which appear to have been too much neglected; and brought others which have been over-rated to their proper standard." Zoroaster would have no cause to be ashamed of this latest offering to the flame of his altar.

E. J. Holmyard.

Researches in Aerodynamics

(1) *Hydro- und Aeromechanik nach vorlesungen von L. Prandtl.* Von Dr. O. Tietjens. Band 2: *Bewegung reibender Flüssigkeiten und technische Anwendungen.* Pp. viii + 299 + 28 Tafeln. (Berlin: Julius Springer, 1931.) 23 gold marks.

(2) *Handbuch der Experimentalphysik.* Herausgegeben von W. Wien und F. Harms. Unter Mitarbeit von H. Lenz. Band 4: *Hydro- und Aerodynamik.* Teil 2: *Widerstand und Auftrieb.* Herausgegeben von Ludwig Schiller. Pp. viii + 443. (Leipzig: Akademische Verlagsgesellschaft m.b.H., 1932.) 41 gold marks.

(1) Dr. Tietjens has performed a very valuable service in writing his two books, based on the lectures of Prof. Prandtl at Göttingen. This second volume deals mainly with the motion of viscous fluids, and the treatment of the subject follows the lines of Prandtl's lectures, but Dr. Tietjens has amplified certain sections, particularly those dealing with the flow in pipes and with the drag of symmetrical bodies, and has added a final chapter describing experimental apparatus and technique. The book contains perhaps little that is new to the student of the subject, and for the greater part it gives a critical descriptive account of the observed phenomena and the corresponding theory rather than the details of the theoretical analysis. The great merit of the book, however, is the excellent account of the physical basis of the boundary layer theory, of the significance of evanescent viscosity in determining the nature of the flow even when the surface friction itself is negligible, and of the fundamental principles underlying the theory of the lift of an aerofoil.

The chapters dealing with the flow in pipes, with boundary layers, and with the drag of symmetrical bodies are perhaps the most interesting and comprehensive; but exception must be taken to the statement that there is a laminar boundary layer below the turbulent flow over the surface of a body, since it rests solely on an attempt to apply rigidly the semi-empirical power law for the velocity

distribution of turbulent flow and is not in accordance with the actual physical conditions. The final chapter on experimental methods contains a brief historical account of the development of wind tunnels and a description of the various modern types. Particular attention is also devoted to the methods of making the flow visible, and there is an interesting series of photographs showing the development of turbulence behind a bluff body and of circulation round an aerofoil.

(2) This volume of the "Handbuch der Experimentalphysik" is devoted to the subject of the lift and drag of a body moving through a fluid, and more particularly to the experimental methods of measuring these forces. All the articles attain a high standard, being comprehensive in character and clear in expression, but it is perhaps to be regretted that experiments in flight, apart from deceleration tests of airships, receive only the briefest attention.

Flachsbart contributes an interesting historical account of the development of hydrodynamics, confined mainly to the determination of drag and the necessary experimental apparatus, and this is followed by an article by Prandtl on the design and operation of modern wind tunnels, in which he expresses a preference for the open jet type in spite of its poorer economy of power. Seiferth and Betz discuss the method of testing aeroplane models in a wind tunnel, describe the principal types of balance used in these tests, and give a few typical experimental results. The problem of wind tunnel interference is discussed in detail, but unfortunately there appears to be some misapprehension on the subject. The authors seem to assume incorrectly that the corrections in open and closed tunnels of any shape are of the same magnitude but opposite sign, and in discussing the interference on the downwash behind an aerofoil they fail to realise that the method of images remains valid for a rectangular tunnel, though it breaks down for a circular tunnel.

Muttray contributes an excellent account of the measurement of the drag of symmetrical bodies, both directly and by measurement of the flow in the wake, and he gives a critical account of the experimental results available. Dropping tests of spheres and discs are discussed very ably by Schiller, who concentrates on the lower range of Reynolds's number, whereas Muttray deals mainly with wind tunnel tests on a larger scale. Schiller also gives a critical discussion of the problem of the sphere, including a summary of the theoretical work on the subject, and shows that the most reliable experiments confirm the accuracy of Goldstein's extension of Oseen's solution with Faxen's correction for wall interference. The final article is devoted to the problem of lubricated bearings, and Kiesskalt gives a clear account of the subject, including a brief summary of the theory initiated by Reynolds and developed by Duffing.

Short Reviews

Introduction des théories de Newton en France au XVIII^e siècle avant 1738. Par Prof. Pierre Brunet. Pp. vii + 355. (Paris: Albert Blanchard, 1931.) 55 francs.

The eighteenth century witnessed the bitter controversies between the Cartesian and the Newtonian conception of the physical world. For decades, the Cartesians tried all the subtleties of logic and science to defend the vortex theory against the views based on universal attraction. But in the end, they had to give way; and the popular defence of Newton's philosophy by Voltaire marked the turning of the tide. It is the epic of these controversies which Prof. Brunet describes for us with a wealth of details giving a scholarly interest to his exposition. The opposition of the Cartesians can be explained by the fact that their master's theory was the first universal explanation of the world, independent of the occult forces which were in favour during previous centuries. The scientific atmosphere of the time was quite at ease with the mechanist conception of Descartes, and loathed any system which had even a vague resemblance to occult qualities. No doubt these controversies help to clear the implications of Newton's system of the dogmatic blemishes which had to be ultimately recognised in Descartes' cosmology. In bringing to light such and other important points, Prof. Brunet has rendered a great service to the history of science. T. G.

More Essays of Love and Virtue. By Havelock Ellis. Pp. xiii + 218. (London: Constable and Co., Ltd., 1931.) 7*s*. 6*d*. net.

Mr. Havelock Ellis began writing books more than thirty years ago, and some of his books might be described as milestones on the way to a more scientific and therefore a saner outlook upon certain aspects of human life. He tells us that his earliest book, having first been received with howls of execration, is now called sane and reasonable. Here he writes again, as indeed he has always written, of love and virtue—meaning by these not crude sex and namby-pamby goodness, but something heroic. He writes of the new mother, the renovation of the family, the function of taboos, the "revaluation of obscenity", the control of population, and the future of eugenics. Whether the reader agrees with Mr. Ellis or not, he feels himself in the hands of one who is master of his theme, and master also of a felicitous literary style. Few people, we imagine, could read the preface to these chapters without reading on to the end.

A World of Epitomizations: a Study in the Philosophy of the Sciences. By Prof. G. P. Conger. Pp. xiv + 605. (Princeton, N.J.: Princeton University Press; London: Oxford University Press, 1931.) 22*s*. 6*d*. net.

THE progress of scientific philosophy seems to be based on rather peculiar assumptions. Run away from substance but hang on to structures, is the slogan that would characterise them best. Yet, in turning its back on Plato and Aristotle, scientific philosophy runs the risk of becoming finally a meaningless logomachy. This tendency seems to us to be interestingly illustrated in the book under review, in which the author, in order to explain structures by other structures, finds himself compelled to adopt a language of his own, to which one may easily take exception for the sake of clarity if not of value and truth.

It is a matter of convenience to divide the cosmos into the three realms of matter, life, and mind, and to discover in them parallel configurations ranging from simpler to more complex ones. But it seems to us misleading to call 'monads' the structures characteristic of each of these configurations. What the author calls "epitomization by monads or by analogy" is the classification of the various 'monads' according to their significant resemblances. This general methological frame enables him to marshal an amazing wealth of details and philosophical or scientific pronouncements into a convenient place in the development of our knowledge. In this he has perhaps performed a useful work, in so far as it enables us to see, almost at a glance, the possible connexion between sometimes widely different theories. But such an epitome of science scarcely explains science itself, which should be the object of philosophy. The hypothesis of epitomisation, if considered as a metaphysics, could not help us to advance one inch towards any philosophical results. "Synoptic naturalism", by which the author defines his position, is merely a term, and the few remarks made about it at the end of the volume are apt to kindle one's curiosity rather than to satisfy it. But perhaps the author does not mean to expound any metaphysics at all—at least, as it is understood in the Greco-Roman tradition.

Recent Advances in Botany. By E. C. Barton-Wright. Pp. viii + 287. (London: J. and A. Churchill, 1932.) 12*s*. 6*d*.

THE "Recent Advances" series of books published by Messrs. Churchill have made for themselves a definite niche in modern scientific literature. Such volumes, written by active scientific workers, must prove invaluable especially to advanced university students of the subjects concerned.

Botanical literature, even that in English, from the point of view of the keen student, has developed into such a maze that it is almost impossible to keep into close touch with all recent important discoveries.

This volume will help such students considerably. The subject matter, controversial though it may be, is presented fairly and references for further study are given at the end of each chapter. The recent theories of form and size are given a prominent position and modern views on palæobotany, species, Fungi, Algæ and virus diseases are considered. Coming from this author, one cannot restrain a feeling of disappointment at the meagre space allotted to plant physiology.

Despite several defects, especially with regard to choice of material (and even this is purely a matter of individual opinion) one can say that the book should be available to all advanced students of the subject.

Glastechnische Tabellen: Physikalische und chemische Konstanten der Gläser. Unter Mitwirkung von H. Alterthum, Chr. Andresen-Kraft, D. Badt, E. Berger, W. E. Flesch, M. Fritz-Schmidt, H. G. Frühling, B. Lange, G. Liebmann, T. Liepus, J. Löffler, M. Reger, A. Russ, R. Schmidt, J. Völker, W. Weyl. Mit besonderer Unterstützung der Deutschen Glastechnischen Gesellschaft E. V. Herausgegeben von Prof. Dr. Wilhelm Eitel, Prof. Dr. Marcello Pirani, Prof. Dr. Karl Scheel. Pp. xii + 714. (Berlin: Julius Springer, 1932.) 149·80 gold marks.

THIS volume of more than seven-hundred pages of summarised information must be admitted as a super-production. The very names of the three co-editors are sufficient to guarantee a book of eminence, and their long list of collaborators of standing is proof of the thoroughness with which the quickly growing literature on glass technology has been combed for data.

The book was planned in 1928, in which year it received the blessing of the Deutschen Glastechnischen Gesellschaft, since which time the editors and their colleagues must have been exceptionally industrious, for information has been collected from about 2500 original papers. It has been examined and sifted, only that which appeared sufficiently precise and reliable being included. Not a single paper containing information capable of being expressed by numbers or diagrams appears to have been overlooked.

The first section of three into which the book is divided, deals with the constitution of glass from the point of view of the 'phase' theory. Temperature-concentration equilibrium diagrams are given for all the systems that have been worked out. Though such diagrams cannot of course refer to true glasses, but only to devitrified glasses, they do help towards an understanding of the constitution of glass. In the second section, the whole range of physical properties—together with the chemical durability—are treated systematically. Where the compositions of the glasses, referred to in Section 2, are known with a sufficient degree of accuracy, they are included in and compose the third section. The usefulness of the book is increased by the inclusion at the end of each subsection of detailed references to the literature on the subject.

S. E.

Chemistry in Space

THE chief impression left by the first meeting of Section B (Chemistry) of the British Association at York on Sept. 1, was the soundness of the foundations on which stereochemistry has been built. After thirty years of revolution in our ideas of the nature of the physical world, the basic conceptions of chemistry need little modification and their assimilation into the body of the new atomic physics only gives them a clearer meaning and a wider usefulness.

This is well exemplified by the first of the two main themes to which Dr. W. H. Mills devoted his presidential address, namely, the value of the tetrahedral atom model when expressed in terms of the electronic theory of valency. The three dimensional extension of the octet theory can be simply represented in a diagrammatic manner by placing the four pairs of electrons at the corners of a tetrahedron concentric with the atom under consideration. Another atom, linked by a pair of electrons, will be situated on the axis through the corresponding axis of the tetrahedron. This tetrahedral octet can only be expected to give a general indication of configuration; since atoms are deformable and valencies can be deflected, it cannot be used, for example, to predict accurate values of intervalency angles. Qualitatively, however, it is able to represent the stereochemistry of all compounds formed in accordance with the octet rule.

When such compounds contain only links composed of two electrons, then it is invariably found that a four co-ordinate atom has a tetrahedral configuration, a three co-ordinate atom a pyramidal configuration, and a two co-ordinate atom an angular configuration. This is illustrated by the configurations of methane, ammonia and water in Fig. 1.

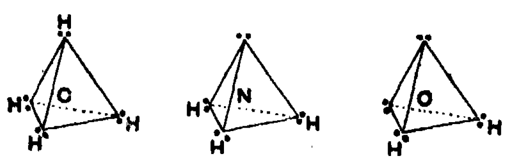

FIG. 1.

The tetrahedral type covers not only the familiar carbon compounds but also accounts for the optical activity of substituted ammonium ions of the type $[Nabcd]^+$, of amine oxides, and of four co-ordinate complexes of beryllium, copper and zinc. The pyramidal formula is, of course, in harmony with the structure of ammonia deduced from its dipole moment and infra-red spectrum; it also accounts naturally for the isomerism of the oximes, the optical activity of sulphoxides and sulphinic esters observed by Kenyon and Phillips, and for the recent resolutions of the *aci*-forms of secondary nitroparaffins. The latter are of particular interest since they probably contain a tri-covalent carbon atom with a pyramidal configuration. (Fig. 2.)

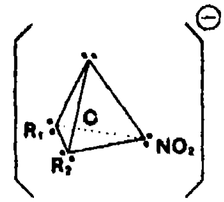

FIG. 2.

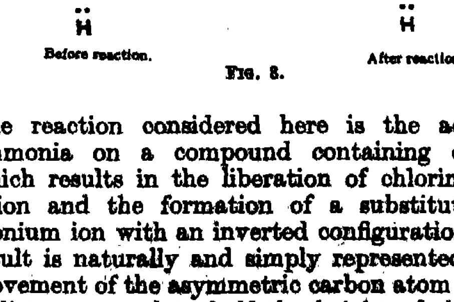
The outstanding difficulty in this group of compounds is the persistent failure to resolve amines of the type *Nabc*. Prof. J. Meisenheimer's contribution to the discussion was concerned mainly with this point; he showed that no resolution is obtained with compounds in which one of the nitrogen valencies is attached to oxygen, namely, in hydroxylamines and in quinoline oxide. Negative evidence of this kind may, as Sir William Pope remarked, have little or no significance and must be very cautiously interpreted; on the other hand, there is some spectroscopic evidence for the view that the nitrogen atom oscillates through the plane containing the attached groups and so makes it impossible to isolate an optically active product.

The idea of the movement of a critical atom to a new permanent position in the molecule was shown by Dr. Mills to give a simple and natural interpretation of three important stereochemical problems, namely, the Walden inversion, the *trans* elimination of water from aldoximes, and the *trans* Beckmann change. The mechanism by which the first of these changes is brought about can be represented very simply by the formulæ in Fig. 3.



Before reaction. After reaction.

FIG. 3.

The reaction considered here is the action of ammonia on a compound containing chlorine, which results in the liberation of chlorine as an anion and the formation of a substituted ammonium ion with an inverted configuration. This result is naturally and simply represented by the movement of the asymmetric carbon atom through a distance equal to half the height of the tetrahedron. The critical point in this explanation is, of course, the attack of the ammonia molecule on

the correct face of the tetrahedron, since attack at any other face would not give the inverted configuration. The electrostatic fields due to the dipole moments of the C—Cl link and the N—H link will give a directing effect and the movement of the carbon atom in this direction will most readily facilitate the escape of the chlorine ion. Thus the velocity of reaction at the proper face will be favoured and inversion will be almost complete.

The formation of benzonitrile from the β-form of benzaldoxime acetate is represented in Fig. 4. The essential reaction is the removal of the elements of acetic acid; this is brought about readily by the action of alkalis on the β-form in

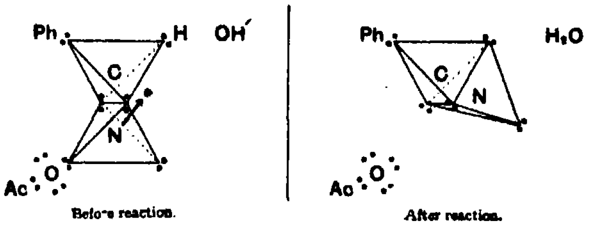


FIG. 4.

which the acetyl group and the hydrogen are on opposite sides of the molecule. The first step is the removal of a proton by union with a hydroxyl ion. The second is the movement of the nitrogen atom into line with the carbon atom to form the linear grouping of benzonitrile. This movement is directly away from the acetate group, which is, therefore, liberated as an ion. The movement of the nitrogen atom in the acetate of the isomeric α-oxime would not be in a direction away from the acetate group; hence the isomeride which reacts most readily must have the *trans* configuration in accordance with the modern view.

This conception of the movement of critical atoms gives a particularly neat explanation of the *trans* Beckmann change. It is usual to think of the migration of groups. If, however, we consider the change occurring in an isolated molecule and remember that moment of momentum must be conserved, it is clear that most of the movement by which the relative displacement is brought about would be executed by the nitrogen atom. Fig. 5 indicates the alternative movements of the nitrogen atoms corresponding with *cis*- and *trans*-migration, and show that the latter is much more probable. The driving force which brings about the change is probably the affinity of the oxygen for the central carbon atom. The first step would therefore be the attachment of the oxygen atom to this carbon atom, followed, or accompanied by the migration of the nitrogen atom. As the diagram shows, this could readily occur to give *trans*-migration, whilst *cis*-migration would involve the passage of the nitrogen atom across the line of closest approach of the oxygen atom to the central carbon atom. The *cis*-interchange of groups, instead of being an assumption which could be taken for granted, is a highly improbable hypothesis and the natural course of the reaction is that leading to *trans*-interchange.

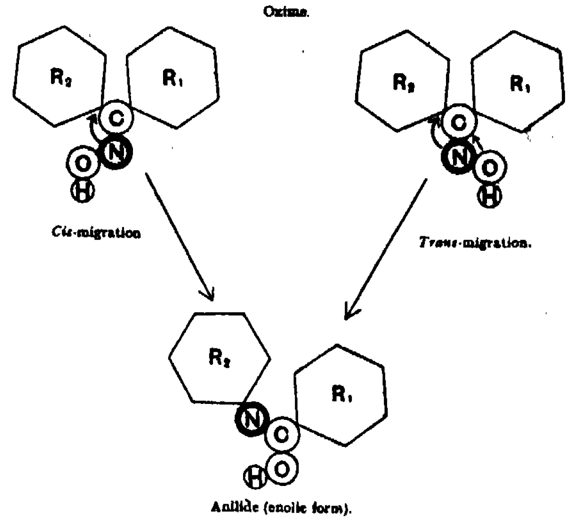

FIG. 5.

The second part of Dr. Mills's address was concerned with the problem of the optical activity of living matter. Pasteur was inclined to ascribe this to cosmical causes and later workers have invoked the influence of circularly polarised light. Dr. Mills suggested, however, that the production of dissymmetric products by living tissue is intimately connected with the characteristic property of growth which differentiates living matter from dead.

The synthesis of dissymmetric products in living tissue involves, at least in its later stages, reactions between dissymmetric substances. Such reactions are known to be stereo-specific and the velocity of the reaction is much greater with one of the optical forms than with the other. This stereospecificity is observed in comparatively simple compounds and can readily be accounted for by the shape and disposition of the parts of the molecule; in the favoured reaction the groups which react can more readily be brought into juxtaposition. With enzyme reactions a high degree of specificity is found and these reactions undoubtedly play an important part in the growth of living tissue.

From a detailed analysis of simplified models of growing tissue, Dr. Mills concludes that the optical activity of living matter is an inevitable consequence of its property of growth. Owing to the stereospecificity of the later changes, any small lack of balance between the *d* and *l* forms of the first dissymmetric product in the chain of reactions would rapidly increase and the dissymmetric tissue would grow more rapidly and soon be present in the growing organism in overwhelming amount. "The mystery of living matter seems to lie in its power of growth. Given this, the optical activity of its components appears to follow as a necessary consequence of the law of mass action and the stereospecificity of interactions between dissymmetric compounds." S. S.

Food Preservation *

RESEARCH has shown the importance of freshness in food. For an industrialised nation, living in large towns, this is not always easily ensured, even in the case of home-grown supplies, and the difficulty is greatly enhanced when the food must be transported long distances before it reaches the consumer. Refrigeration has provided an empirical solution, but our knowledge, especially on the biological side, is as yet inadequate to ensure that the subtle properties of freshness are sufficiently conserved. Research on the preservation of food is therefore of the utmost importance to the inhabitants of Great Britain; but in spite of the fact that the food imported in 1931—comprising the greater part of the wheat and fruit consumed, half the meat, poultry, eggs, and dairy produce, and a smaller proportion of the fish and vegetables—cost about one million pounds a day, the amount spent on research by the Food Investigation Board during 1931 was less than £50,000.

The necessity for economy has led to a reduction in the Board's expenditure, but the staff has not been reduced. Owing to the specialised nature of the work, losses of personnel cannot immediately be made good when circumstances warrant an expansion of the Board's activities, so that reduction of staff would delay the resumption of normal progress to an extent out of all proportion to the economy effected.

Food investigation is of value, not only to the consumer, but also to the producer both at home and in the Empire overseas. The Board has received financial assistance from the Empire Marketing Board, and co-operation with other parts of the Empire is ensured by the presence of representatives of the Dominions, India, and the Colonial Office, sitting as assessors, at the Board's meetings. The experimental work on the cold storage of food has now reached a stage when the results obtained can be transferred to the full commercial scale. The co-operative survey of the New Zealand frozen lamb industry, which was mentioned in last year's Report and full details of which are about to be published, was so successful that the Board felt that this collaboration should be continued. A Consultative Group has therefore been formed, comprising the Director of Food Investigation (Sir William B. Hardy) and members of his staff, the assessors mentioned above, and representatives of the shipping lines nominated by the Chamber of Shipping of the United Kingdom and the Liverpool Steamship Owners' Association.

The Report is this year arranged in four parts, describing respectively the researches carried out at the Low Temperature Research Station, at the Torry Research Station, and at the Ditton Laboratory, the three research stations of the Board; the fourth part deals with extramural researches carried out at the National Physical Laboratory and the Imperial College of Science and Technology. The different sections deal with meat, bacon, fish, fruit, and vegetables, as well as problems of biological engineering and canning. Each is written by the investigator who has carried out the research described, and presents the results obtained in a form which is best described as that of a detailed summary. References are given to the original papers from which fuller information may be obtained. It is not possible here to do more than refer to one or two of the more important points raised by the Report; but it is hoped to consider certain other aspects at a later date.

A preliminary survey of the problems associated with imported edible offal has been carried out by T. Moran. It was found that there is scope for improvement in grading and preparation, packing and freezing. Evaporation of water appears to be the most serious problem. These tissues are of importance for the preparation of certain medicinal products, and at present the Dominions supply only a negligible fraction of the total imported for this purpose. Prompt freezing after removal from the animal is essential, and no opportunity for thawing during storage and transport must be permitted. In New Zealand, a further difficulty has to be overcome, since the demand is almost exclusively for ox's glands at present, mainly on account of their size.

It has been shown by E. H. Callow that the transport of unsmoked mild-cured bacon from Australia and New Zealand is impracticable under existing commercial conditions, since the fat becomes rancid after less than two months' storage even if a temperature so low as $-10°$ C. is used. Gas storage may be the solution of this problem, since the rancidity is due to the fact that the fat takes up oxygen even at this low temperature. On the other hand, carcasses of frozen pork can be transported successfully and used as pork or for the manufacture of bacon. It has also been found that smoking retards the subsequent development of rancidity, whatever the temperature of storage, within the range 15° C. to $-20°$ C., but cannot prevent it entirely.

In the case of fish, it has been found that after freezing in brine, it is necessary to store at temperatures so low as $-20°$ to $-25°$ C. instead of the usual $-4°$ to $-12°$ C., if alteration in the fish is to be prevented. Fish stored at the lower temperature can be smoke-cured: hitherto one of the objections to frozen fish has been that it is quite unsuitable for smoking. The conditions required for properly smoking haddocks and herrings have been examined by A. Lumley. To give a 'finnan' finish to the former, seven hours' smoking was necessary, the temperature being gradually raised from 80° to 90° F., and the relative humidity being less than fifty per cent at 80° F. To produce a 'kipper' it was necessary to extend the time of curing to twelve hours and to raise the temperature to 95° F. for one hour and to 100° F. for the final hour. Most of the smoking in commercial practice is carried out by rule-of-thumb methods. It is suggested that the incomplete control and the length of the process

* Department of Scientific and Industrial Research. Report of the Food Investigation Board for the year 1931. Pp. x+293. (London: H.M. Stationery Office, 1932.) 5s. net.

is the reason why so many dyed kippers are on the market: dyed herrings can be smoked in 5-6 hours.

Work has been continued on the gas-storage of apples in the experimental stores at the Ditton Laboratory. At present, control over the composition of the atmosphere is obtained by regulated ventilation with fresh air, but there is now some evidence that a closer control over the percentages of oxygen and carbon dioxide in the store may be required in the case of certain varieties. Experiments have also been carried out on the gas storage of pears and bananas and the cold storage of potatoes. J. Barker has found that between $+3°$ and $-1°$ C. there is a great increase in the amount of sugar found in the potato after sixty days' storage, the concentration being inversely proportional to the temperature. The sweetening is attributed to a change in the organisation of the protoplasm. It was also found that transference from a low temperature to 15° C. for a period of only twenty-four hours completely arrested any further increase in the sugar content in the cold store.

Most fruits and vegetables undergo autolytic changes when hard frozen, even at $-20°$ C., the only exception so far observed being raspberries. On thawing such frozen raspberries, colour and flavour were perfect and the texture was scarcely altered. Blanching will permanently inhibit these changes: after blanching, peas, runner beans, and potatoes can be frozen, and on thawing again are superior to the canned vegetables. Strawberries can be frozen in syrup at $-20°$ C., and the thawed fruit is suitable for fruit salads, etc. Plums and cherries, treated similarly, turn brown on thawing; they can, however, be frozen after blanching.

Work has been continued on the corrosion of iron and tin. It has been found that ferrous salts accelerate the corrosion of tin in the presence of air by acting as carriers of oxygen. Ferric salts accelerate the corrosion of iron in the presence of air over the range of hydrogen ion concentration likely to be met with in the canning of fruit, the combined effect of air and the ferric iron being much greater than that of either of them alone, especially at a hydrogen ion concentration of about *p*H 4. Further work has also been carried out on the engineering and physical problems of the maintenance of temperature and composition of the atmosphere in stores such as ships' holds. In the storage of fruit, the metabolism of the fruit itself affects both the temperature and atmosphere of the store, and complicates the problem of maintaining a constant environment.

International Astronomical Union

THE fourth general meeting of the International Astronomical Union, attended by representatives of twenty-four countries, was held at Cambridge, Massachusetts, on Sept. 2–9, under the presidency of Sir Frank Dyson. At the opening session the Union was welcomed by the Hon. C. F. Adams, Secretary for the Navy in the United States cabinet, and by Dean Bernice Brown, head of Radcliffe College. The members of the Union were for the most part accommodated in the dormitories of the College, a very convenient arrangement giving every opportunity for the informal discussions in small groups which add so much to the real value of the meeting. The full meetings were held in the Alice Longfellow Hall of Radcliffe College, and the commissions met in the various lecture rooms. All the arrangements for the meeting were made with a thoroughness and completeness, which it would be difficult to equal, by a local committee with Prof. Harlow Shapley as chairman and Mr. L. B. Andrewes, following the late Miss Adelaide Ames, as secretary.

The formal work of the Union lay in the sessions, reports and resolutions of twenty-seven committees: these dealt with such subjects as meridian astronomy, planetary observations, *Bureau International de l'Heure*, variation of latitude, *Carte du Ciel*, stellar parallaxes, variable stars, stellar spectra —to mention only a few of them. The volume of draft reports is nearly two hundred pages long and can scarcely be summarised here, but reference may be made to the reports on solar physics, by Dr. St. John, on standard wave-lengths by Prof. A. Fowler, on stellar photometry by Dr. Seares, on radial velocities by Dr. J. S. Plaskett, and on the observations of Eros for solar parallax, by Dr. Spencer Jones.

Among resolutions passed by the General Assembly were the following: The equinox of 1900·0 was adopted for catalogues other than catalogues of precision, by agreement among the various groups of astronomers interested in the question. A proposal to fill a gap existing in astronomical bibliography between 1880 and 1899 was approved. A proposal to establish the vertical circle of the Pulkovo Observatory in as nearly equal a southern latitude as possible in the hope of improving fundamental declinations, met with much sympathy and full approval. A number of recommendations adopting fresh standard wave-lengths and urging further work on the subject was adopted. The printing of a list of designations for lunar formations was approved. Further exploration of the meteor craters in North Africa and Siberia was urged, also an extension of the meteor work now being carried on in Arizona. A resolution from the commission on radial velocities earnestly commending any project for obtaining urgently needed data in the southern sky, and welcoming the possibility of establishing a large reflector in South Africa in the event of the transfer of the Radcliffe Observatory, was passed unanimously by the General Assembly. Financial help was granted towards the printing of further volumes of the *Carte du Ciel*. Other grants were continued mostly at a reduced figure, and a new grant was made toward the reduction of the Eros observations.

On the proposal of the finance committee the unit of subscription from the adhering countries was lowered. It was hoped that this might check any further secessions of countries on financial grounds, Australia and South Africa having resigned on that score. Two new countries—India and the Vatican State—were reported as adhering since the last General Assembly, while Roumania had become a fully subscribing member of the Union. As in the number of countries adhering, so also in the numbers of commissions there were changes. The commission on dynamical astronomy was abolished at its own request, while new commissions on 'Selected Areas' and spectrophotometry were formed. The solar commission broke up once more into its earlier constituent parts in the form of commissions on sunspots, chromospheric phenomena, solar spectroscopy and radiation and eclipses.

In addition to the technical discussions and the international organisation in the commissions there was an interesting visit to the Harvard College Observatory and to its new station at Oak Ridge for a 61-inch reflector; later a demonstration was given of eclipse results so far as they could be announced. Good results may be expected apparently from chromospheric spectra obtained by the falling plate method by the Lick observers, and a very nice flash was secured by the Greenwich observers—the only British expedition in Canada which had any luck at all. Nice pictures of the corona were secured by a number of expeditions, notably the Lick party which also at last obtained some interference fringes from the coronal line. Good polarisation results are hoped for from the French and the Harvard expeditions. Amongst other interesting slides shown at the meeting were the coronal spectrograms and photographs secured by M. Lyot, of the Paris-Meudon Observatory, without the aid of an eclipse.

The next meeting of the General Assembly was fixed for 1935 (probably early July) in Paris on the invitation of the French astronomers. The newly elected executive committee to serve until then consists of Prof. F. Schlesinger (United States), *President*; Prof. T. Banachiewicz (Poland), Prof. E. Bianchi (Italy), Prof. C. Fabry (France), Prof. N. E. Norlund (Denmark), Prof. F. Nušl (Czechoslovakia), *Vice-Presidents*; Prof. F. J. M. Stratton (Great Britain), *General Secretary*.

Recent Researches on Cosmic Rays

IN the *Times* of October 8, Prof. A. Piccard gives an account of his experiments on the cosmic rays during his balloon ascent on August 10, in which he was accompanied by Max Cosyns, and reached a maximum height of 53,672 feet. Two distinct types of observations on the cosmic rays were made on this occasion, one to determine the variation of intensity of the rays with height, and the other to determine the distribution of the radiation in different directions.

The observations on the change of intensity were apparently made in the usual way by measuring the ionisation produced in a sealed vessel. Prof. Piccard states that his results over the same range of height are in good agreement with those found by Prof. Regener, of which an account was given in a letter published in NATURE of September 3. It will be recalled that in Regener's experiments, self-registering apparatus was attached to a free balloon which reached a much greater height than Piccard's balloon. He found that the intensity of the radiation increased rapidly at first with altitude, then more slowly, and finally reached what appeared to be a constant maximum at the greatest heights. The free balloon of Regener rose to a point where the barometric pressure was about 25 mm., while the lowest pressure reached by Piccard was 73 mm. The concordant results obtained by the two observers thus give us new and valuable information of the apparent variation of intensity of the rays up to the highest altitudes that are likely to be reached for some time to come.

The second type of experiment made by Piccard was to determine the direction of the cosmic rays by using a tubular Geiger counter. This device has the property of distinguishing to some extent between rays coming from different directions. At the earth's surface it can be shown with this apparatus that the rays come predominantly downwards. In striking contrast to this, Piccard finds no such directional effect at high altitudes, and thus concludes that the radiation at such great heights is uniform in all directions. He provisionally suggests that the cosmic rays have their origin in the stratosphere. He is, however, careful to point out that this is not the only possible explanation. For example, little if any directional effect would be expected if the rays were actually cosmic in origin and fell on the earth uniformly in all directions. Whatever may be the ultimate interpretation of these observations, they constitute an important contribution to our knowledge.

A vigorous attack on the problem of the nature of the cosmic rays is now being made by several new and powerful methods. The experiments of Regener and Piccard afford trustworthy information of the variation of intensity of the rays with altitude, while the work of many experimenters has given us accurate data of the absorption of the radiation for great depths of water and for other absorbing material. The earlier observations of Millikan had indicated that the intensity varied little if at all on the earth's surface. This important question has been again examined by Prof. A. H. Compton during the past year in the course of his travels in the northern and southern hemispheres. He made observations of the relative intensity of the cosmic rays by the ordinary ionisation method. He concludes that there is a marked change of intensity at different parts of the earth, especially

for the softer components of the radiation. In a recent communication to the *Physical Review* (Sept. 1, 1932) he concludes that there is a definite correlation between the intensity of the cosmic rays and the direction and magnitude of the earth's magnetic field. The intensity in general is higher the greater the angle of magnetic dip. The dependence of the intensity of the cosmic rays on magnetic latitude has also been convincingly shown by Clay and Berlage from continuous observations on a voyage from Amsterdam to Batavia.

Such a relation between intensity of the rays and the earth's magnetic field is to be expected on general grounds if the radiation consists of a stream of swift charged particles. It will be remembered that Prof. C. T. R. Wilson long ago suggested that the cosmic radiation may originate from thunderstorms in our atmosphere. In the intense electrical fields that precede a lightning flash, it is probable that electrons and other charged particles may acquire a very high velocity. If some of these pass out into space, their paths will be bent by the earth's magnetic field and a few may eventually re-enter our atmosphere. In the light of the new observations, such a possible origin of the cosmic radiations should not be overlooked. In this connexion, it should be noted that Schonland in South Africa has found that the intensity of the rays is suddenly altered by the occurrence of distant lightning flashes, but no such effect is observed immediately beneath the thundercloud.

The question of the nature of the cosmic rays is still a matter of much discussion—whether, for example, the primary radiation is of the γ-ray type or consists of a stream of fast electrons or protons—but there seems to be a growing belief that the main part of the radiation is corpuscular in character. This question is now being actively investigated by photographing the tracks of the ionising particles in an expansion chamber and observing the curvature of these tracks due to a strong magnetic field. By this method Millikan and Anderson have found that not only are swift electrons present, but also positively charged particles believed to be swift protons. Many of these particles undoubtedly have energies corresponding to several hundred million electron volts. Blackett and Occhialini (NATURE, Sept. 3, 1932) have made experiments of a similar kind using an ingenious device whereby the passage of an ionising particle through two Geiger counters in line is made to actuate an expansion chamber, placed between the counters, within a hundredth of a second of the passage of the radiation. By this device the accumulation of data should be much more rapid. By the full use of these powerful methods, we may hope soon to obtain definite information as to the nature and energy of these ionising particles, and of the effects produced by them in their passage through matter.

Reference should also be made to another strange type of occurrence observed with the cosmic rays. Hoffmann and Steinke and Schindler have observed sudden bursts of ionisation in a measuring vessel, of a magnitude far exceeding that produced by the swiftest α-particle known. It has been suggested that these bursts of ionisation arise from some type of disintegration process brought about by the cosmic rays: whatever may be the explanation, there can be no doubt these observations suggest a fascinating if difficult field for further research. It should be mentioned that Compton, in his recent experiments already referred to, noted that these bursts of ionisation are much more frequent at high altitudes, and suggested that they may be due mainly to an effect of the softer components of the radiation.

The problem of the origin and the nature and properties of the cosmic rays is one of the most interesting in the domain of physics. It is to be hoped that the concentrated attack from so many different directions will soon bring more definiteness to our knowledge of this obscure type of radiation.

Obituary

MR. WILLIAM G. COLLINGWOOD

THE death of William Gershom Collingwood, artist, archæologist and author, at the age of seventy-eight years, took place at Coniston on Oct. 1. The son of a well-known landscape painter, W. Collingwood, he was born at Liverpool on Aug. 6, 1854, and matriculated at University College, Oxford, in 1872. While at Oxford, where he took first class honours in *Literæ Humaniores*, he formed a close friendship with Ruskin, then Slade professor, and when the health of the latter broke down, accompanied him abroad to France and Italy, later settling near him at Windermere. Here he occupied himself in landscape painting, editing Ruskin's works and lecturing on the theory and history of art. After Ruskin's death he was for some time professor of art at the University of Reading.

In Cumberland Collingwood had come into contact with members of the Cumberland and Westmoreland Antiquarian Society and had been attracted to the study of Icelandic literature and the archæology of the Norse settlements in the north of England. The first fruits of his studies, however, took the form of fiction, his first novel appearing after a visit to Iceland in 1897. Ill-directed criticism of his second venture "The Bondwoman", notwithstanding its high literary merit, diverted him to a more intensive study of the Norse and Anglian archæology of northern England, especially on its artistic side, upon which he became widely recognised as the first authority. A long series of papers in the *Proceedings of the Antiquarian Society*, of which he became editor, culminated in the publication of an exhaustive and

standard work on "Northumbrian Crosses" (1927), in which a knowledge both wide and profound was combined with keen insight and artistic feeling. Although to the general public "The Life and Work of John Ruskin" among Collingwood's writings will be his strongest claim to remembrance, "Northumberland Crosses" is his most enduring achievement. Under his editorship the *Proceedings of the Cumberland and Westmoreland Antiquarian Society* attained a standard of technical and artistic excellence unusual among the publications of local scientific societies; and he was the inspiration and the organiser of much of the excellent work in archæological research which has been accomplished by the Society in the present century. In 1920 his work was recognised by election to the presidential chair.

MR. H. C. CHADWICK

WE regret to announce the death of Mr. Herbert Clifton Chadwick on Sept. 16 at the age of seventy-three years. He was the last survivor of a group of scientific men who, in the 'eighties of the last century, began the biological investigation of the Irish Sea region. For this purpose the late Sir William Herdman founded the Biological Station at Port Erin, in the Isle of Man, and Mr. H. C. Chadwick, then a business man in Manchester and an amateur naturalist, was made curator of the laboratories. He was a recognised authority on the morphology and systematics of the Echinodermata and was the author of many papers on these subjects. But his general zoological knowledge was very wide and in his capacity of curator of the Port Erin Station he was able to assist very many investigators and students who worked there during the last forty years.

WE regret to announce the following deaths:

Prof. Karl E. Ritter von Goebel, For. Mem. R.S., professor of botany in the University and Director of the Botanical Gardens, Munich, an authority on cryptogamic botany, especially Bryophyta and ferns, on October 10, aged seventy-seven years.

Dr. T. H. C. Stevenson, formerly superintendent of statistics at the General Register Office, who rendered great service in the field of vital statistics, on September 12, aged sixty-two years.

Prof. William Stirling, formerly Brackenbury professor of physiology in the University of Manchester and in 1906–9 Fullerian professor of physiology at the Royal Institution, on October 1, aged eighty-one years.

Dr. Florence A. Stoney, formerly demonstrator in anatomy at the London School of Medicine for Women, who was a pioneer in X-ray and ultra-violet light treatment, on October 7, aged sixty-two years.

Sir Everard Im Thurn, K.B.E., formerly curator of the British Guiana Museum, and in 1919–20 president of the Royal Anthropological Institute, on October 8, aged eighty years.

News and Views

Antony van Leeuwenhoek, 1632-1723

ON October 24, 1632, four days after the birth of Sir Christopher Wren at East Knoyle, Wiltshire, the tercentenary of which has just been celebrated, Antony van Leeuwenhoek, the eminent Dutch naturalist who has been called the "Father of Protozoology and Bacteriology" was born at Delft. Both Wren and Leeuwenhoek were long associated with the Royal Society in its early days, and both lived to extreme old age; Leeuwenhoek outliving Wren by six months and dying at Delft on August 26, 1723, being then aged—as his epitaph says—"90 years, 10 months, and 2 days". But the careers of these two distinguished men followed very different lines; for while Wren was first a professor of astronomy and then a great architect, Leeuwenhoek began his life as a draper and haberdasher with few advantages of education, and his fame came through his lifelong devotion to microscopical studies. The son of a basket maker, he was sent to a school at Warmond, near Leyden, and at sixteen was an apprentice in Amsterdam. At the age of twenty-two years he married and set up in business for himself in his native town, and for thirty-nine years was "Chamberlain of the Council-Chamber of the Worshipful Sheriffs of Delft". He was also a surveyor and wine gauger. When he began his work with his simple microscopes is not known, but at the age of forty-one years he addressed the first of his many letters to the Royal Society, then eager to get into touch with all men working for "the promotion of natural knowledge", and it was through these letters he became famous. He was made a fellow of the Royal Society in 1679 (1680 N.S.), a *correspondant* of the Paris Academy of Sciences in 1699, and in 1716 the University of Louvain presented him with a medal. At his death at Delft in 1723 he was buried in the Old Church, in which his daughter Maria, in 1739, erected a monument to his memory.

Leeuwenhoek and the Royal Society

THE connexion of Leeuwenhoek with the Royal Society was unique, since, although for fifty years he was a constant correspondent and for forty-three years a fellow, he never attended a single meeting. His letters were all written in old-fashioned Dutch and before publication in the *Transactions* were translated into English or Latin. They were none the less highly appreciated and many distinguished men visited Delft in order to see the writer of them. He, indeed, became one of the 'sights' of the pleasant town. In spite of his wonderful discoveries and his communications to the Royal Society, hitherto there has been no good account of his career in English.

But the three-hundredth anniversary of his birth is happily marked by the publication by Prof. Clifford Dobell of a handsome volume entitled "Antony van Leeuwenhoek and his 'Little Animals' being some Account of the Father of Protozoology and Bacteriology and his Multifarious Discoveries in these Disciplines". Prof. Dobell has been called Leeuwenhoek's "greatest living admirer" and his book is worthy of his hero. How he was led to the study of Leeuwenhoek's letters in the original Dutch, what difficulties he met with and how these were gradually overcome are set forth in an entertaining prefatory epistle, while after this come chapters dealing with the life of Leeuwenhoek, his observations on protozoa and bacteria, his microscopes and methods of work, his language, his writings and other matters. Leeuwenhoek appears to have been singularly free from prejudice and in one of his letters wrote: "As I aim at nothing but Truth, and so far as in me lieth, to point out Mistakes that may have crept into certain Matters; I hope that in so doing those I chance to censure will not take it ill; and if they would expose any Errors in my own Discoveries, I'd esteem it a Service; all the more, because 'twould thereby give me Encouragement towards Attaining of a nicer Accuracy."

Australian National Research Council

At the annual meeting of the Australian National Research Council held in Sydney in August, it was determined to make a special effort to secure further financial support for the chair of anthropology which was established in the University of Sydney some time ago through the activity of the Council. The existence of the chair is threatened by recent reductions in government grants. In recognition of the work of its first two presidents, Sir T. W. Edgeworth David and Sir David Orme Masson, the Council has established two lectureships to be awarded alternately at two year intervals, the David lectureship, commencing in 1933, to be devoted to geology or biology, the Masson lectureship, commencing in 1935, to physics or chemistry. A bronze medal in honour of Sir Thomas Ranken Lyle, the retiring president, is to be struck and it will be awarded not more frequently than every second year to such Australian worker in mathematics and physics as may appear to the Council to be worthy of the honour. The incoming officers are: *President*, Sir George A. Julius; *Vice-Presidents*, Sir William Mitchell, Dr. A. C. D. Rivett, Prof. N. T. M. Wilsmore, Prof. H. C. Richards; *Secretary*, Mr. A. J. Gibson; *Treasurer*, Dr. H. G. Chapman; *Executive Committee*, Sir Douglas Mawson, Profs. Agar, Watt, Osborn and Goddard, Drs. Waterhouse and Dickson, and Messrs. Andrews, Gepp and Wainwright.

A long discussion as to the future policy of the Australian National Research Council and its relationship to the International Research Council took place at the annual meeting. The standing of the Council as a national academy of sciences for the Commonwealth was reaffirmed and, with the object of stimulating its working in certain respects, the executive committee was requested to introduce such changes in constitution and by-laws as might be necessary to give effect to the following objects:—(1) the institution of a very limited fellowship; (2) the appointment of distinguished overseas scientific workers who have been associated with science in Australia as honorary overseas fellows; (3) migration of headquarters between capital cities; (4) alteration in rules of appointment to the executive committee to ensure more frequent changes in personnel and to effect closer contact with Royal Societies and other scientific bodies; (5) the display of greater initiative and leadership in the attack upon major problems associated with science in Australia, the Mandated Territories and the Australian quadrant of the antarctic continent; (6) the devising of practical means for bringing members in all centres into more intimate touch with the handling of these problems; and (7) the formation of a committee to explore the possibilities of a federation of Royal Societies and certain other scientific organisations in Australia.

Exhibition of Inventions

The eighth International Exhibition of Inventions organised by the Institute of Patentees (Incorporated) was opened at the Central Hall, Westminster, on October 5 by Sir Maurice Jenks, the Lord Mayor of London. The opening was followed by a luncheon at St. Ermin's Restaurant, when Lord Askwith, president of the Institute, remarked that it is not the old men, but the young, who are bringing marvellous things into the world. As in former years, the exhibition is divided into two main sections, a trade section which includes many things already on the market, and a section of new inventions, the latter being sub-divided into groups of exhibits relating to domestic and labour-saving appliances, electrical and radio apparatus, building and housing details and mechanical apparatus. As might be expected, the last of these groups contains many new devices for motor vehicles such as brakes, lights, signalling signs and means for preventing cars being stolen. One interesting exhibit is a small electrically driven model boat in a tank for demonstrating the increase in efficiency of the propeller obtained by surrounding it with a ring of approximately cone section. Other exhibits relate to internal combustion engines and to variable speed gear and transmission gear.

A Reversing Centrifugal Gear

Among the last group of exhibits in the Inventions Exhibition is the new epicyclic gearing invented by Prof. F. Soddy, the main object of which is to provide for the transmission of large powers at high speed, and for reversing without declutching. The gear in one form or another is therefore suitable for use with steam turbines or high-speed marine engines. Unlike most epicyclic gears, there are in it no toothed wheels. The driving and driven shafts are co-axial. On the end of the driving shaft are

two cranks at 180° apart and these drive two heavy 'planets', which have a slight freedom of movement in a radial direction relative to the crank pins. When the shaft is revolved at high speed, the planets are thrown outwards by centrifugal force and their outer surfaces come into contact with the inner surface of a fixed annular casing around which they begin to roll. The disc of each planet is pierced with circular holes and in these fit loosely a corresponding number of rollers and studs carried by discs on the driven shaft. It is through these that the power is transmitted. The gear can be arranged so that if necessary the second shaft is fixed while the casing revolves, while by using planets of a different design the gear can be made reversible. The exhibit attracted considerable attention and it is to be hoped will soon be tried on a large scale.

A Dinosaur from Montana

During the past summer, a party from the American Museum of Natural History, under the leadership of Mr. Barnum Brown, has explored the Cretaceous rocks of Montana in which remains of fossil reptiles occur. According to a message from the New York correspondent of the *Times* which appears in the issue of Oct. 1, it has found a nearly complete skeleton of the armadillo-shaped dinosaur *Nodosaurus*, which has hitherto been known only from fragments. The reptile is remarkably broad, for although it is only 14 ft. long, it is 7 ft. wide at the hips. It is heavily armoured with bony plates, which are arranged to give flexibility to the trunk and tail. It has feeble teeth adapted for feeding on either vegetables or insects. *Nodosaurus* was first recognised and named in 1889 by the late Prof. O. C. Marsh, who received characteristic pieces of it from his collectors in the Cretaceous rocks of Wyoming. A somewhat similar fossil skeleton, without head, was discovered in 1913 by the late Mr. W. E. Cutler in corresponding deposits in Alberta, Canada, and it is now exhibited in the British Museum (Natural History). It was named *Scolosaurus cutleri* by Baron Nopcsa, who published a restored drawing of it by Miss Alice B. Woodward in the *Illustrated London News* of Sept. 11, 1926. *Scolosaurus* must have been about 12 ft. long, and would be only about 3 ft. high when walking. A smaller reptile of the same group was found long ago by the late Rev. William Fox in the Wealden formation in the cliffs on the south coast of the Isle of Wight, but he was able to recover it only in a rather fragmentary state. It was named *Polacanthus foxi* by Hulke, and is now also exhibited in the British Museum (Natural History).

Memorial to the Late Sir Andrew Balfour

On October 6 the Earl of Athlone, Chancellor of the University of London, unveiled a memorial tablet to the late Sir Andrew Balfour, first director of the London School of Hygiene and Tropical Medicine, in the entrance hall of the School. The tablet, which is of polished Roman stone with a bas-relief head in bronze, is the visible part of a twofold memorial, the other purpose being a scheme to enable students, preferably those from overseas, to pursue courses of study at the School. At the ceremony the Chancellor paid a well-deserved tribute to Sir Andrew and his world-wide work in the cause of tropical medicine and public health. Referring to the organisation of the London School of Hygiene and Tropical Medicine he said: "To that work which was, alas, to prove the last of his labours—the building, the equipment, the organisation of this great School—Andrew Balfour brought the same passionate zeal, the same untiring energy which were characteristic of his whole career, and his inspiring personality is so very fresh in the minds of all of you that of his last great piece of work there is hardly any need to speak. The appointment of Andrew Balfour to be the first Director of this School gave to the School from its very inception a splendid introduction throughout the whole world and contributed perhaps more than anything else to the reputation which it has already established. Finally, and in a word, Balfour was a great Empire builder; and when I say this I am thinking not so much of his devotion to work, of his vast knowledge and contributions to the subject of Empire health, not of his academic distinctions, not of his contributions to sport and literature, but of his fine character. He was without guile, honest to the core, a man who evoked in his colleagues a spirit of love and sacrifice." It is fitting that the memorial tablet bears the quotation from Walt Whitman which Balfour himself loved:

> "Through the battle, through defeat, moving
> yet and never stopping,
> Pioneers! O pioneers!"

Excavations in Westmeath, Ireland

Exceptional interest is attached to the finds which have been made by the Harvard University Archæological Expedition in excavating a crannog at Ballinderry, near Moate, Co. Westmeath, Ireland, and an early bronze age cairn at Knockast nearby. The excavations are in charge of Dr. H. O'Neill Hencken, whose recent book on Cornwall in the "County Archæologies" series, has given him an assured place among authorities on British archæology. The crannog was first identified by Dr. Adolf Mahr, of the National Museum of Ireland, some four years ago, when a Viking sword was found in the course of cutting a drain across the bog. The island constituting the crannog is built up of layers of brushwood and peat contained by timber piles, on which lay a substructure of massive timbers supporting further layers of peat and brushwood and the floor of a circular dwelling. Above this, and built some time later, were two smaller rectangular houses. Judging from the animal remains, the inhabitants were both hunters and herdsmen, while the coulter of a plough and querns indicate their practice of agriculture. In place of pottery they used well-turned wooden vessels, made on a lathe, and barrels made of staves and hoops. Among the tools and weapons of iron was a Viking battle-axe. The remains are dated at about A.D. 1000. The

most remarkable finds were a hanging lamp and a gaming board. The former is described by a correspondent of the *Times*, who gives an account of the discovery in the issue of Oct. 7, as "the finest bronze which has yet come to light in excavation in Ireland". It is a pointed oval, with three hanging chains attached to animal heads, and is decorated with rosettes and an acanthus scroll. It will be interesting to hear Mr. Kendrick's analysis of its relation to the British hanging bowls, from which descent is claimed for it. The wooden gaming board has forty-nine holes and is bordered with carved Celtic patterns, said to be the finest Viking object known from Ireland.

Television Broadcasting

THE transmissions from Broadcasting House, London, of television by the Baird process have fulfilled the expectations of the radio engineers. Some think that this may lead to the revival of the 'puppet' show which was very popular about two hundred years ago. The London transmissions have been seen well in Scotland, a distance of more than 400 miles. At present two bands of radio frequencies are required in the overcrowded ether, one for the visual and another for the sound signals. In *Television* for September A. P. Peck describes a new system of broadcasting developed by the Columbia Broadcasting Company of New York which uses only one wave for both sight and sound signals and thus makes a smaller demand on the available channels in the ether. A low-powered 45 kc. (kilocycle) oscillator is used in the first instance for the sound signals, the wave being modulated by the sound programme coming from the television studio. The sound modulated current includes frequencies up to 5 kc. on each side of the carrier wave. The wave with the television signals occupies the band on the frequency spectrum ranging from 2750 to 2850 kc. The sound signal is actually radiated on two sub-carrier waves with frequencies of 2755 and 2845 respectively. With this arrangement the Columbia engineers have got satisfactory results. Not only does the method save space in the ether but it also saves equipment at each end. It is a great advantage to the average 'looker in' to have a receiver for both sight and sound which is compact, not easily damaged and simple to operate.

Revised Standard Frequency Radio Transmissions

THE modern extensive use of radio communication of all types demands for its success that each transmitting station shall keep very exactly to its allotted wave-length or frequency, so that interference with transmissions on neighbouring wave-lengths may be reduced to a minimum. At the present time the majority of commercial radio transmitting stations on land, including those employed for broadcasting purposes, use in their installation a source of oscillations the frequency of which is accurately controlled by means of a tuning fork or piezo-electric crystal. In order that the administrations to which these stations belong may be able to measure and adjust their wave-lengths very accurately, it is necessary that their controlling apparatus may be frequently checked against some national or international standard. It was to meet this need that on behalf of the Radio Research Board of the Department of Scientific and Industrial Research, waves of accurately known frequency have been transmitted for some years past from the wireless station at the National Physical Laboratory for checking the calibration of wavemeters and other apparatus.

THE programme of transmissions has recently been revised and the main standard now employed consists of a single frequency of 1,000 cycles a second. This frequency is derived from an installation which is maintained in continuous operation, day and night, at the National Physical Laboratory and serves as the national standard of Great Britain. This low frequency standard is emitted in the form of a modulation on a carrier wave the nominal frequency of which is 360 kc./s. (wave-length 830 m.). A regular monthly programme of such transmissions is now maintained by the National Physical Laboratory to enable all those desirous of doing so, to receive the transmission and to make a comparison between their own frequency standard and that of the Laboratory. In addition, a second quarterly programme of standard frequency transmissions consisting of a controlled carrier wave of frequency 1785 kc./s., is still maintained by the Laboratory, largely for the benefit of amateur experimenters. Those interested in this work can obtain a copy of the programmes of transmissions on application to the Secretary, Department of Scientific and Industrial Research, 16 Old Queen Street, Westminster, London, S.W 1.

Pharmacy and Recent Advances in Science

THE opportunities which the present rapid advances in science offer to the student formed the text of the address delivered by Dr. C. W. Kimmins at the opening of the School of Pharmacy of the Pharmaceutical Society of Great Britain on Oct. 5. For the scientific research worker there are all sorts of important problems awaiting solution. A student of organic chemistry frequently encounters puzzles such as this: a substance is known as a natural product of great medicinal value; the chemist works upon it and finds that a substance can be produced synthetically apparently exactly similar, yet the physiological properties may differ in a marked degree. Many of these problems of the different action of synthetic and natural substances have been solved, but delightful fields for research remain. Even in a limited field, to have extended the bounds of human knowledge must ever be a source of intense gratification to the worker. To take another example, in physical analysis, scientific workers at one time concentrated exclusively on the elements of the visual spectrum; but of late years a great transformation has taken place. Men of science are concentrating on the larger wave-lengths on one side and the smaller wave-lengths on the other, with the relative neglect of the intermediate wave-lengths. When the ultra-violet part is successfully

charted and carefully studied it will cast a wonderful flood of light on physiological processes, especially upon the growth of plants, so many of which are materially affected by stimuli associated with minute wave-lengths. With such advances in science and the solution of previously apparently insolvable problems, it is not to be wondered that the enthusiastic student of to-day has developed a spirit of adventure unknown in former days.

The Giant Horntail Borer

A short time ago a cinema picture of the giant horntail borer (*Sirex noctilio*) and its parasite (*Rhyssa persuasoria*) was shown in the theatres of New Zealand. This picture was of especial interest to the Dominion, since it was upon the researches into the biology of these insects in England on behalf of the Cawthron Institute, Nelson, that the picture was based. Owing to the widespread establishment of *Sirex* in the exotic coniferous forests, particularly of *Pinus radiata*, in New Zealand, Sir Guy Marshall, of the Imperial Institute of Entomology, was approached by Dr. D. Miller, and as a result, the former arranged with Dr. Thomspon, of the Empire Marketing Board's Parasite Laboratory at Farnham Royal, for a study to be made of the parasite *Rhyssa* in order that supplies might be secured and sent to New Zealand. This has been done and the parasite liberated in its new environment. The actual life-history studies on *Rhyssa* were undertaken by Dr. Chrystal, of the School of Forestry at Oxford, where the picture was made. It is work of this nature, especially when presented to the public in picture form, that forcibly demonstrates how dependent the overseas Empire States are upon the assistance of such institutions as the Imperial Institute of Entomology and the Farnham Royal Parasite Laboratory.

Antiquities from the Thames

A question of considerable interest to archæologists was raised at a meeting of the Thames Conservancy Board on October 10 in connexion with a report by Prof. Elliot Smith on a human skull and bones of late bronze age which had been dredged from the bed of the Thames below Hampton Court Bridge. A letter was presented from the Council of the London and Middlesex Archæological Society asking that articles of archæological interest from the bed of the Thames should be deposited with the museums of the county in which they were found, and suggesting that objects found in Middlesex should be deposited at the Brentford Museum. The decision of the Board was to refuse the request on the ground that it was felt that all relics from the Thames should be together in the possession of the Board. The opinion of a majority of archæologists would probably be in favour of the claims of local museums in this matter; but there is much to be said for the single collection, in view of the character of the Thames as a highway of culture from very early times. This argument, however, loses force when it is remembered how many antiquities from the Thames already lie scattered in various museums and collections. The most cogent consideration is the accessibility of the material for purposes of study. Apart from the suggestion of loans to museums from time to time, Lord Desborough, as chairman, could only hold out the vague hope that the Conservancy might be able to display its collections at some indefinite future time when space might become available. It is very desirable that the collection now in the possession of the Thames Conservancy should be accessible to students. A statement from the Board as to how far this is possible, and if at all, in what conditions and under what regulations, would be welcome.

Industrial Organisation

Arrangements have been made by the Governing Body of the Imperial College of Science and Technology for the delivery during the present session of a series of special lectures on various of the productive industries by lecturers whose experience will enable them to speak with authority. The lectures will be given in the Huxley Building of the Royal College of Science, Exhibition Road, S.W.7 on certain Thursdays at 4 p.m., and will be open to all members of the College staff and students. The lectures during the autumn term will be by Dr. Herbert Levinstein, on the chemical manufacturing industry (Oct. 27); Mr. Austin Hopkinson, on the advantages of the small industrial organisation (Nov. 17); Mr. Maurice Solomon, on the electrical industry with special reference to the advantages of the large industrial organisation (Dec. 1); and Mr. G. M. Burt on the building industry (Dec. 15). Particulars of the lectures during the spring term will be announced later; but they are expected to treat of (*a*) the heavy engineering industry, (*b*) the textile industry, and (*c*) the steel industry. It is intended to publish the seven lectures in a volume.

The immediate object of the lectures is to give Imperial College students, many of whom enter manufacturing industries after graduation, an idea of some of the bigger problems, of whatever nature, which confront manufacturers at present, and to suggest what the future may have in store, either in the way of technical improvements, or as a result of national and international developments. In taking this step the Governing Body has been prompted by the feeling that, in this time of world depression, the considered views of the manufacturer have not been sufficiently heard. The lecturers have accordingly been chosen from distinguished men in control of particular branches of the productive industries, and able therefore to speak with authority upon the subjects with which they will deal.

Training in Industrial Management

The increasing complexity of industrial management, together with the intensification of world competition, seems to call for the more effective training of managers and industrial executives than has been usual in the past. To meet the special requirements of 'industrial scientists', a course of training in industrial management is to be started by Mr. W. R. Dunlop at 57 Gordon Square, London. The aim is to supplement the basic scientific training

of the physicist, chemist, biologist or engineer with a training in the methods, functions and problems of industrial and business management. The course extends over a period of three months and covers "The Function and Problems of Industrial Management", "Sciences underlying Industrial Management" and "The Mental Activity of Industrial Management."

"Current Science"

WE have often commented on the increased interest which is being shown in science in India and further evidence of this is afforded by the issue of a new scientific monthly, *Current Science*, the first two parts of which have now been received. The journal, which is published at the Indian Institute of Science, Bangalore, under the direction of a strong editorial board, is modelled on NATURE both in its format and in the arrangement of its contents. The first two numbers contain editorials on "Retrenchment and Education" and "Unemployment among the Educated Classes". The former is of general interest, the latter, however, deals with a problem peculiar to India and one which has arisen mainly from the adoption of a university degree as a means of entry to Government service. The problem is now acute and without doubt steps will have to be taken to raise the degree standard in Indian universities and simultaneously to institute Civil Service examinations. Other articles of interest are "The Study of Nutrition in India" by Col. R. McCarrison and "Chemistry and Currency" by Dr. Gilbert J. Fowler. Numerous short scientific communications appear in the form of letters to the editor and there are short abstracts of recent publications in other journals. We welcome the appearance of this new monthly; if the standard of the first two issues is maintained it will be a valuable addition to scientific literature.

Automatic Temperature Control

WHEN the temperature during an industrial process must be kept constant it is more economical to do it automatically than by hand, and in a thirty-page pamphlet issued by Messrs. Negretti and Zambra methods of control are described. They depend on mercury in steel thermometers in which the capillary tube ends in a Bourdon tube which uncoils as the temperature of the bulb of the thermometer rises. This actuates a mercury switch if the heat supply to the furnace or chamber is electrical, or a compressed valve in a two-atmosphere air supply leak if the heat supply is gas or liquid. The change of pressure of the air supply operates a valve in the gas or liquid supply pipe.

Announcements

THE Secretary of State for the Colonies has appointed Mr. P. C. Chambers to be agricultural officer, Kenya.

THE Thomas Hawksley Lecture of the Institution of Mechanical Engineers will be delivered by the Right Hon. Lord Rutherford on Nov. 4, at 6 P.M. Lord Rutherford has chosen as his subject "Atomic Projectiles and their Applications".

MR. H. J. PAGE has been appointed controller of the Agricultural Research Station of Imperial Chemical Industries, Ltd., at Jealott's Hill, Bracknell, Berks, following the release of Sir Frederick Keeble from his executive and routine duties at that Research Station. Mr. Page was until 1927 head of the Chemical Department and chief chemist at the Rothamsted Experimental Station, and since that time has held the position of head of the Research Laboratories and chief chemist at the Research Station of which he has now taken charge.

AT the annual meeting of the Yorkshire Naturalists' Union to be held on Dec. 10, it is proposed to present to Mr. Thomas Sheppard, director of the Hull Municipal Museums and editor of the *Naturalist*, the official organ of the Union, his portrait in oils by Mr. Vincent Galloway. The presentation is to mark the retirement of Mr. Sheppard from the editorship of the *Naturalist* and as an appreciation of his work in that capacity for the last thirty years. Subscriptions may be sent to the Hon. Treasurer, The Yorkshire Naturalists' Union, Sackville Street, Leeds.

AN award of the Harrison Prize will be made next December by a committee consisting of the presidents of the Chemical Society, the Institute of Chemistry, the Society of Chemical Industry and the Pharmaceutical Society. The Prize is of the value of about £150 and is awarded to the chemist who, in the opinion of the Selection Committee, during the last five years has conducted the most meritorious original investigations in any branch of pure and applied chemistry and has published his results. Further information can be obtained from the President, The Chemical Society, Burlington House, Piccadilly, London, W.1.

A MOVEMENT is on foot among the engineering profession to mark in an appropriate manner the centenary, in April next year, of the death of Richard Trevithick, one of the greatest of British engineers. A meeting of representatives of engineering institutions will be held on October 20, at 5.30 P.M. at the Institution of Civil Engineers, Great George Street, Westminster, S.W.1. Engineers generally who are interested in the proposal are cordially invited to attend. The movement was started by the Newcomen Society for the Study of the History of Engineering and Technology, the honorary secretary of which is Mr. H. W. Dickinson, Barn Field, Riddlesdown Road, Purley, who will be pleased to answer inquiries.

APPLICATIONS are invited for the following appointments, on or before the dates mentioned:—A lecturer in biology at the Bishop Otter College (Church of England) for Women Teachers, Chichester —The Principal (Oct. 24). A director (professor) of the Research Laboratory in Zoology and a director (professor) of the Research Laboratory in Biochemistry at the University of Madras.—The Registrar, University of Madras, Triplicane, P.O., Madras (Dec. 1).

Letters to the Editor

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, nor to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

The Oldoway Human Skeleton

IN NATURE of June 18, 1932, page 903, Prof. D. M. S. Watson and C. Forster Cooper discuss further the question of the Oldoway human skeleton. I should be grateful for space to reply to certain points raised by them.

They state: "Dr. Leakey now claims that the skeleton was buried in Bed 2 before Bed 3 was deposited over it. This involves the supposition that the deposition of the materials of Bed 2 took place in water so shallow that a bedding plane was at one time exposed to air and sufficiently dried to allow men to walk over it and dig a grave in it." I simply cannot agree that any such supposition is necessarily involved. Bed 2 *is* a shallow water deposit and its surface may have dried up as they suggest; but there is another explanation equally possible: that the body of Oldoway man was deposited into the deposits of Bed 2 *under water*. Even to-day in certain circumstances, some native tribes dispose of the bodies of undesirables, such as suicides, in just such a way, "so as to prevent the spirit from escaping". Possibly the idea of a burial under water had not occurred to my critics.

Concerning the rate of erosion, my own estimate is that at a time less than fifty years before Prof. Reck came to Oldoway, the site where he found the skeleton was covered by a deposit consisting of a very small relic of Bed 3 overlain by Bed 5 and the steppe lime. The rate of erosion can be estimated fairly accurately from certain facts, and if anything, I believe my estimate is on the conservative side. Moreover, I do not remember ever having mentioned "survey pegs inserted by Prof. Reck in 1913"; for they do not exist. What we did find were the stumps of the corner posts of the hut erected by Prof. Reck over the skeleton while he was working on it. Experiment shows that these posts, if they were to hold the weight of the hut, must have been inserted at least eight inches into the ground, and the hut was erected on the flat. When we found them, erosion *on the flat* had been such that one of the post stumps had fallen and the others were sticking a bare two inches into the ground. In other words, erosion on the flat had been about six inches between 1913 and 1931.

Actually, of course, erosion does not go on at a constant rate, but the cliff face has receded between 1 ft. 6 in. and 2 ft. since Reck was there in 1913. If Prof. Watson and Mr. Forster Cooper had seen the site, I cannot believe that they would still contend that the skeleton represents a relatively recent burial.

I agree that the mere fact that the bones of the Oldoway skeleton are as much mineralised as others from Bed 2 (though less so than bones from Beds 3 and 4) is of itself evidence of no great value, but I would like to point out that Messrs. Mollison and Giesler, after a very careful study of the amount of organic matter remaining in the bones, formed the conclusion that the skeleton was not younger than Magdalenian. I would further point out that, so far as I understand them, Messrs. Mollison and Giesler do not dwell on the resemblances to the Masai. Their argument is rather that "as we find certain Oldoway characters among Hamites it is quite possible that these characters are of old standing in Africa and form one element (perhaps mixed with negro) among the Hamites". This is very different from a statement that Oldoway man resembles the Masai who still inhabit the district.

My criticisms and replies to other points raised in the letter must be reserved for our detailed report. I must, however, add that I do regard the discovery of the Kanam mandible and the Kanjira skulls as relevant to the Oldoway problem, in that they at least show that *Homo sapiens* was in existence at the time when Bed 2 at Oldoway was being formed.

L. S. B. LEAKEY.

(Written in camp at Oldoway. Aug. 14, 1932.)
P.O. Box 40,
Limuru,
Kenya Colony.

HAVING recently visited Oldoway, and having studied the geological sections there displayed, especially with the view of evaluating evidence for or against the Bed 2 age of Oldoway man, I am deeply interested in Prof. Boswell's letter in NATURE of Aug. 13, under the above title, and I should like to offer the following remarks.

Average samples of the beds were taken and these were studied in the laboratory by Mr. W. C. Simmons, senior assistant geologist on my staff, who has considerable experience of such work, and from my own investigations and the work of Mr. Simmons I personally have no objection to the post-Bed 4 age of the human remains. Indeed, field studies have inclined me to the view that Oldoway man is probably of Kenya Aurignacean date, and from personal knowledge of the site I am persuaded that he is pre-steppe limestone. Prof. Boswell and Dr. Solomon have, I consider, shown the human fossil to be younger than Bed 4, but I contend they have not done more than that; at any rate, it would so appear from the former's letter. The fact that the matrix from between the ribs contains bits of concretionary limestone containing a mineral characteristic of Bed 4 does not prove the burial to be post-Bed 5, for Bed 4 contains concretionary limestone, and for that matter so do the other beds, not excluding Bed 2, a fact to which I particularly directed Dr. Leakey's attention.

Lubricating Oils and Cancer

IN connexion with a recent note on emulsification,[1] Mr. W. T. Astbury has directed our attention to the latest report of the Manchester Committee on Cancer. According to the *Times* abstract from this report, "the addition of a small quantity of saponifiable oil to the lubricating oil reduces markedly the number of tumours induced. No oil surpasses lanolin in this respect. The substitution of lanolin for castor oil as a protection for oil workers has markedly lessened dermatitis among them, particularly if the workers

are young". A striking parallel exists between these results and the data obtained for the removal of mixed oils from wool. It has been shown that mineral oil is extremely difficult to remove from wool by emulsification, owing to high oil-water interfacial tension and high adhesion. The difficulty can be overcome by the addition to mineral oil of polar compounds which reduce the oil-water interfacial tension without increasing adhesion so far as to make emulsification difficult. Fatty acids, and glycerides such as olive oil, were found to be ineffective compared with oleyl alcohol, which causes ready emulsification in 6 per cent concentration. Similarly, certain alcohols from lanolin may be used to confer emulsifiability on mineral oil, a mixture containing 15 per cent being emulsified with as much ease as olive oil.

The parallel between these two sets of results suggests that the incidence of dermatitis and tumours may be caused by the difficulty of removing mineral oil from skin by means of soap solution, and that lanolin is effective only in so far as it affects emulsifiability. Working on this hypothesis, Prof. R. D. Passey, director of cancer research of this University, has commenced experiments with mixtures of mineral oil and polar compounds possessing the necessary critical oil-water interfacial tensions. The inherent probability of the view that ease of removal of mineral oil from skin must lessen the risk of cancer formation, impels us to say that, on the basis of the work on emulsification, mixtures of mineral oil and derivatives of wool fat were prepared for use on textile machinery, but simply on account of their improved lubricating properties and ready emulsifiability. The possibility of such mixtures being non-carcinogenic was in no way foreseen.

Inheritance of Acquired Characters

THE interesting letter from A. F. Dufton in NATURE of Oct. 1, p. 508, suggests a statistical method of study of the possible transmission to the offspring of mental characteristics acquired during their life by their parents, the possibilities and limitations of which seem to have been little explored or discussed. Mr. Dufton takes the age distribution of the fathers at the birth of 1000 eminent persons from the fourteenth edition of the "Encyclopædia Britannica", and shows that these ages are distinctly higher than the ages of the fathers of 100,000 children less than one year of age at the Census of Scotland in 1921. At first sight the inference might be drawn from this fact that the superior ability of the children was due to the increased wisdom acquired by their parents during their experience of life; but, before drawing this conclusion, there are one or two preliminary points to be considered.

(1) It is certain that during the relevant period the upper and middle classes married on the average some few years later than the general population. Presumably, the ages of fatherhood in these classes were also somewhat retarded. If, as one might suppose, the 1000 eminent persons chosen by Mr. Dufton came disproportionately from these classes, this alone would explain the greater age of paternity. A more satisfactory comparison would be between the ages of paternity for the eminent persons, and those of their less eminent brothers and sisters. This reduces itself to a comparison between eminent and non-eminent persons from the same families according to order of birth.

(2) In comparisons between selected and unselected children according to order of birth, great care is unfortunately necessary to eliminate the effects of death in childhood. It is a mistake to assume, for example, that corresponding to every sixth child, there is one child of each preceding birth order, who might equally have become eminent. In families of six or more, some of the first five children will have died before attaining an age at which their talents might have raised them to eminence. Again, among families terminated voluntarily, the sex ratio of the last child must be much disturbed in favour of males, and more than half of the 1000 eminent persons are doubtless of this sex. A just comparison will require the proportion of eminent to all the surviving non-eminent, according to birth rank and size of family, for the two sexes separately. Such a tabulation would be full of interest.

(3) Supposing the sociological and statistical difficulties of the comparison were overcome, it would be a matter for further inquiry whether the differences observed (supposing them to be in the same direction as those found by Mr. Dufton) were due to the inheritance of environmental modifications, or to environmental modifications themselves. There is little doubt that children brought up in close contact with others slightly older than themselves are somewhat more precocious (in reading and writing for example, and in acquiring a vocabulary) than others without this advantage. Again, if parents increase in wisdom with years, should not this wisdom be partly applied in improving the upbringing of the later children? I mention these points, not to discourage inquiry into the effects of birth rank, but to show that the specific question of a Lamarckian factor is not more easily disentangled in this than in other modes of inquiry.

(4) Some doubt might be felt whether all forms of capacity do increase greatly with increasing age, say from 30 to 43, to take the quartiles of Mr. Dufton's distribution for the fathers of the eminent. Should we not expect that the fathers of athletes, aeronauts and possibly artists and poets, and any occupations showing enterprise, receptivity and a capacity to learn, should be younger than the average, while those of misers and politicians should be conspicuously older? Opinions will doubtless differ widely as to the position of men of science.

Diamagnetism of Molecules

FOR diatomic homopolar molecules the bond-forming electrons are imagined to be concentrated within the region of the two nuclei and to experience the attractions of the different centres. The resulting torque causes a continual transference of angular momentum between the electron and the nuclei, and, as has been shown by Van Vleck, the average square of the electronic angular momentum, and

hence of the magnetic moment, does not vanish even for ^1S state of the molecule. This causes a loss in diamagnetism the magnitude of which is proportional to the degree of concentration of charge within the region between the nuclei; this concentration is also responsible for the more essential part of the binding energy of a homopolar molecule. Hence for diatomic homopolar molecules we should expect that the loss in diamagnetism on molecule formation will be proportional to the binding energy.

The table given below attempts to test this conclusion. The atomic χ values have been computed by Slater's method. As these values are for isolated atoms, comparison would have been justified if the molecular χ's referred to the gases. Unfortunately, observations are available mostly for solids and liquids. There is also an uncertainty in the spectroscopic determination of the dissociation energy. Considering all those factors, it would seem from a study of the table that the relation holds to a first approximation.

Table I.

	Calc. (atom + atom)	Obs. (molecule)	Percentage loss	Dissociation energy (spectroscopic)	Dissociation energy (thermal)
H_2	4·86	3·99	18	4·42	4·2
C_2	18·82	11·70 (diamond)	37·5	7·0	
N_2	16·20	11·8	27	9·0*	
CN	17·51	11·25	36	9·5	
S_2	44·02	30·72 (rhombic sulphur)	30	4·9	
Cl_2	40·78	40·47	1	2·54	2.47
Br_2	67·56	62·4	7·7	1·96	2·0
I_2	102·86	91·5	11	1·53	1·6

The susceptibility and energy data are taken from the International Critical Tables except * which is from NATURE, vol. 129, 870; 1932). It appears roughly that there is a loss of about four per cent per volt of dissociation energy. Cl_2 does not fall into the scheme. There are reasons for believing that the computed value for I_2 is too high, which if true will improve the agreement. A detailed paper appears elsewhere.

Nuclear Structure

IN a recent note in NATURE,[1] Bartlett has shown that the nuclei of the light elements may be represented by a model built up of appropriate numbers of neutrons and protons arranged in independent groups about an α-particle. It seems very significant that the numbers of protons and neutrons thus assigned to the p- and d-shells are the same as those required by the Pauli Exclusion Principle for electrons. This at once suggests that quantised spins and orbital momenta are also associated with the neutrons and protons in the nucleus. From quite another point of view, Heisenberg[2] has found it necessary to assign a spin, $\frac{1}{2}\cdot\frac{h}{2\pi}$, to the neutron.

Considerable support can be found for such an extension of the model by consideration of the nuclear moments of the lightest elements. To obtain complete agreement with experiment, the following assumptions are necessary :—

(1) The protons and neutrons are independently coupled to the central α-particle; as the α-particle has no spin, the nuclear moment is the difference of the resultant momenta of these two systems.

(2) The protons—attracted to the α-particle owing to the nature of the potential curve for small separations—form a quantised system the state of least energy ('ground term') of which may be predicted by analogy with the similar electronic system, the terms of which are inverted with respect to those of the proton system.

(3) For each neutron, the spin vector is parallel to, and coupled with, the orbital momentum vector. The neutrons form groups of two, with opposed total momentum vectors. In the p-shell, the contribution of each neutron to the resultant moment is $\frac{3}{2}\cdot\frac{h}{2\pi}$.

TABLE.

Nucleus.	Structure.	Component Moments. Neutrons.	Component Moments. Protons.	Nuclear Moment (I).
H1	π	—	$\frac{1}{2}$	$\frac{1}{2}$
He4	α	—	—	0
Li6	$\alpha+\nu+\pi$	$\frac{3}{2}$	$\frac{3}{2}$ ($^2P_{3/2}$)	0
Li7	$\alpha+2\nu+\pi$	0	$\frac{3}{2}$ ($^2P_{3/2}$)	$\frac{3}{2}$
C12	$\alpha+4\nu+4\pi$	0	0 ($^3P_0$)	0
N14	$\alpha+5\nu+5\pi$	$\frac{3}{2}$	$\frac{1}{2}$ ($^2P_{1/2}$)	1
O16	$\alpha+6\nu+6\pi$	0	0 ($^1S_0$)	0

π = proton; ν = neutron.

As the table shows, this model accounts for all the observed moments of the nuclei up to O^{16}—where the p-shell is completed. It is very striking that the nuclear moments of Li^7 ($I=\frac{3}{2}$) and N^{14} ($I=1$) are no longer exceptional.

It is at present not possible to predict the behaviour of the protons in the d-shell, as the screening effect of the six protons of the p-shell is greater than the attraction of the central charge (+2 units).

Absorption of Sound by Porous Materials

SOME time ago, there was a discussion[1] between E. T. Paris and Heyl concerning the dependence of the absorption of sound upon the angle of incidence, which, however, produced no solution to the problem. Since for many practical purposes dependence of absorption upon angle and frequency is very important, investigations have been undertaken in this direction, which confirm qualitatively the angle theory of Rayleigh and Paris and a frequency theory proposed by us.

The relation of absorption to angle of incidence was measured in the open air on the flat roof of the institute. Loudspeaker and microphone were placed directly upon the floor. The sound reflected from the specimen under test was measured and compared with that from a completely reflecting plate (for example, a thick glass plate).

The frequencies used lay between 1,000 and 10,000 Hz., the angle of incidence lay between 10° and 75°. The following materials were tested: Tentest, Celotex B and BB, cotton wool and acoustic board. These materials were generally mounted upon plates of absorbing materials (Insulite). Particularly interesting is a material which functions according to the assumptions of Rayleigh, that is, which consists of a series of parallel lying channels constructed from corrugated paper. By closing a varied amount of surface, for example, changing the number of

channels, the porosity was altered from 0·2 to 0·99. The curves measured for the frequency 5,000 Hz. are reproduced in Fig. 1. These curves correspond in the measured range to the theory of Rayleigh and Paris. For the above mentioned materials, curves were obtained in the specified frequency range, which have the form of the theoretical curves for small and intermediate porosities; cotton wool has curves corresponding to a large porosity.

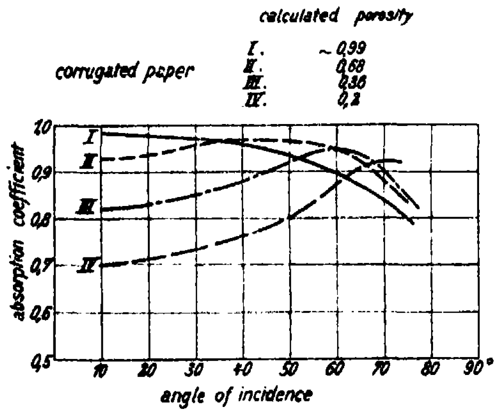

FIG. 1.

Secondly, the dependence of absorption upon frequency was tested. The acoustical impedance was measured for normal incidence in a tube with the help of an electrostatic vibrometer. Theory and experiment show, that the real part of the characteristic acoustical impedance (for infinite thickness) decreases with increasing frequency from a large value to a limit, while the imaginary part decreases to zero. The limit is given theoretically by the expression $\frac{Z_0}{P}$; where Z_0 = acoustical impedance of air and P = porosity. The characteristic limiting impedance of porous materials is always larger than that of air; it follows that a maximum must exist in the above mentioned curves showing the dependence of absorption on the angle of incidence, which is given by the relation $\cos\theta_{\max.} = \frac{Z_0}{Z}$ (Z = impedance of the material). The absorption coefficient increases continuously to a limit and has, therefore, on account of porosity alone no maximum. Selective absorption is explained by interference due to limited thickness. This effect has also been investigated.

Details of this work will be published towards the end of this year in the *Elektrische Nachrichten-Technik.*

Efficiency of Geiger Counter and Absorption of Cosmic Rays

THE efficiency of a Geiger counter may be defined as the probability of excitation when the counter is traversed by a high speed electrified particle. A determination of the efficiency for cosmic rays may be obtained in the following way. Imagine three counters 1, 2, and 3, which are placed with their axes in the same plane and their centres in the same (vertical) line. Let n_{13} be the number of coincidences between 1 and 3 and n_{123} the number of triple coincidences. The efficiency of the counter 2 is then determined by $n_{123} : n_{13}$.

In the experimental arrangement the dimensions of the counters were 5 cm. × 20 cm.; the counters were filled with air at a pressure of 4–9 cm. of mercury. The central electrode was a steel wire treated with nitric acid. The counters were placed in a vertical plane with a distance of 15 cm. between their axes; lead blocks 7 cm. × 10 cm. × 20 cm. could be placed between the counters. Below and on the sides the whole arrangement was screened by 10 cm. of lead in most of the experiments. The method used for recording coincidences has been described previously.[1] It consists essentially in imparting the impulse delivered by the counter to the mirror of an oscillograph. When coincidences between two counters are recorded, the deflections of the two mirrors are crossed, so that when a coincidence occurs the actual deflection makes an angle of 45° with each of the single deflections. In the present experiment it was necessary to use four oscillographs in order to record coincidences between three counters. The deflections of the four mirrors were crossed in such a way that the three possible kinds of coincidences, namely, 1-2, 1-3, and 2-3, were all recorded on the same film.

The smallest time difference which can be detected by this method is 2×10^{-4} sec., corresponding to one-tenth of the duration of the impulse. The number of single impulses from each of the counters was about eighty per minute, the number varying somewhat with the experimental conditions. This gives for the number of accidental coincidences between two counters 0·05 per minute, and for the number of accidental triple coincidences $2{\cdot}4 \times 10^{-5}$ per minute. The number of coincidences actually observed was for neighbouring counters about five per minute and for triple coincidences one per minute. The corrections for accidental coincidences are thus very small.

When the counters were operated at a potential a few volts above the lower limit of the sensitive range of voltage, about half of the coincidences 1-3 were triple coincidences, or, what is the same, the efficiency of the counter 2 was 50 per cent. At a potential 30 volts higher the efficiency was 85 per cent. The statistical material was too small for giving accurate numerical values, but in all experiments the same general result was found, the efficiency approaching unity at the upper limit of the sensitive range of voltage.

The justification for considering the efficiency as a property of the counter and not of the exciting radiation lies in the fact that the results were only determined by the voltage of the counters, and not by the presence or absence of the lead absorbers between and on the sides of the counters. This result has some bearing on the problem of the nature of the cosmic rays. If the cosmic rays were of electromagnetic nature, it seems very difficult to account for the values of efficiency actually observed.

The Contribution of Science to the Future

THE leading article under the above title in NATURE of Sept. 3 is a timely reminder of the outstanding problem of the present age. When science begins to question what is being done with its lavish gifts to humanity, it is a healthy sign, and gives grounds for hope that something may be done towards solving the greatest anomaly of our time—that of scarcity in the midst of abundance, and its attendant evil, unemployment. It is, too, a sign of awakening to the realities of the situation that there were echoes of this question at the recent meeting of the British Association—notably in the president's address and in the suggestive address by Prof. Miles Walker on "The Call to the Engineer and Scientist". Moreover, there are not lacking other signs in various directions that this question is becoming a live issue, and one that must be grappled with, and that quickly.

The question arises, What is the best way of following up these finger-points, and translating them into action?

It may I suppose be laid down as a general proposition that the fruits of science—and they are many—ought to be made available to the community, free of any exacting toll, and in such a way that the benefits are distributed as evenly as possible to every member of the community. Efforts should be directed towards seeing that there is no loss of efficiency between the findings of science on one hand, and their application to human life on the other. Here, if anywhere, should be evidence of the 'conservation of energy' on its highest plane.

Thanks to science, the problem of production has been solved, and by means of a policy of rationalisation, costs have been reduced to a minimum. On the *distributive* side, however, there has been no corresponding advance or change. In the midst of an otherwise changed world, we continue to pursue the same outworn methods of our forefathers of 150 years ago, relying upon the inertia of the past to carry us through.

This disequilibrium between the productive and distributive side of industry, which is the root of the problem, must be righted if civilisation is to reap the benefits of scientific progress. Here more than anywhere else is abundant scope for rationalisation in the proper sense of that rather hackneyed term. Nothing indeed could be more irrational than the existing state of affairs.

The fact is, there has been a sad lagging behind the advance of science on the part of what may be termed the non-scientific world, that is, the ethical and spiritual, and we might add, the political. There has been no preparing of the ground for the coming of the gifts of science, and the result is that much that should otherwise have been a benefit to mankind has simply led to social chaos.

As to what is to be done, a humble suggestion may be hazarded. In these days of over-specialisation, when the general is apt to be lost in the particular, should not an attempt be made to co-ordinate all the leading forces of to-day—scientific, ethical, industrial, political, etc.—by forming some sort of general council, the object of which would be to concentrate upon this special problem of how Nature's gifts, as revealed by science, can best be applied to the welfare of mankind; to plan definitely, and if need be to create, a new order of society, fitted to receive, and make adequate use of, our newly found powers; and further, to tackle the correlative problem of providing for the proper use of that leisure which may be expected to be the outcome of a proper use of Nature's bounties? The one essential qualification for members of such a council would be the possession of those qualities of mind referred to in the article: it may, perhaps, be summed up in freedom from the inertia and prejudices of the past, and an open mind towards the future. The recommendations of such a council could, I feel sure, be made to carry weight in political quarters, and so in time filter through into national life.

Prof. Walker's suggestion of an experimental self-supporting colony under scientific supervision is also worthy of attention.

One is tempted to reflect that if some self-sacrificing genius could be found to devote as much, or even a tithe of the attention and research upon this seemingly recalcitrant problem as is concentrated upon, say, the breaking up of the atom or the origin of life, a solution would not be long in being forthcoming. Is it too much to hope that some such genius may one day be found?

A Biological Conversion of Glucose to Glucosone

WHEN the fully developed mycelium of a certain mould belonging to the flavus section of the *flavus-oryzae* group of Aspergilli, is allowed to act upon a 5 per cent solution of glucose in the presence of a small quantity of toluene, I have observed that glucosone is produced. This may be detected in the medium when the experiment has been allowed to proceed at a temperature of about 27°–28° for several days, the presence of the glucosone being demonstrated by the fact that addition of phenylhydrazine acetate in the cold gives rise immediately to a precipitate of glucosazone. A 5 per cent solution of glucose on treatment with phenylhydrazine acetate in the cold does not yield immediately a precipitate of glucosazone.

The glucosone was also characterised as an azine, which was formed when *o*-phenylenediamine was added to the medium from the culture flask. The derivative melted at 194°–195° and proved to be identical in appearance, composition and behaviour, with the azine obtained by treatment of a solution of authentic glucosone with *o*-phenylenediamine. A mixture of the two specimens also melted at 194°–195°.

This formation of glucosone from glucose under the influence of an enzyme or system of enzymes present in a mould is not without interest in view of the suggestion made by Hynd[1] that the first step in the utilisation of glucose in the animal body is oxidation to glucosone, insulin being presumed to act as an oxidase catalysing the conversion.

Further study is being made of the conditions under which this transformation can be effected by biological agency.

Research Items

Celtic Art in Britain.—A counter theory on Celtic art to that developed by Mr. T. D. Kendrick in his recent advocacy of a Romano-British source for the hanging bowl (see NATURE of July 2, p. 27) is put forward by Dr. R. E. Mortimer Wheeler in *Antiquity* for September. Two main phases of Celtic art in Britain are recognised, a pagan Celtic art beginning in the fifth century B.C., and ending in the second century A.D., and a Christian Celtic art beginning in the sixth century A.D., and lingering on until about the ninth century. Though linked by an essentially similar informing spirit, they are separated by a hiatus of three centuries, a feature rare in the history of a single school of art. Further, when Celtic art reappears after the hiatus, it is not in the dominantly Celtic parts of Britain, but in the pagan Saxon area. Taking the distribution of pagan Celtic art in time and space, it reaches its zenith during the first century B.C., coinciding with the area in which political authority in the island was consolidated, indirectly and afterwards directly, under Roman rule, while north of the Humber the northern school of this art awaits the settled conditions of the second century A.D. In the Christian phase, it was the Saxon settlement and the Saxon peace which afforded the Celtic craftsman the security and leisure he needed for the development of his art, while he was free from the competition of Roman mass production. On this line of thought the sequence of Celtic art becomes logical. On four occasions the Celtic artist was in a sympathetic environment. First in the Belgic and earliest Roman occupation; secondly during the earlier Roman occupation of northern Britain; thirdly during the Saxon settlement of central and southern Britain; and fourthly during the regime of a strong and wealthy church in Ireland; that is, four periods when political and economic security were forced upon the Celts.

Gods of the Acoma.—The Acoma Indians of New Mexico were first visited by whites when Capt. Alvarado was sent on an exploring expedition from Zuñi (Cibola) by Coronado in 1540. They then earned a reputation for unfriendliness which they have maintained until the present day. A study of their culture has recently been published by Mr. Leslie A. White (Forty-seventh Ann. Rep. Bur. Amer. Ethnology). At the head of their pantheon stands Ocato, the sun, the chief of supernaturals. With him are his two sons, Masewi and Oyeyewi, the twin war gods, symbolising courage, strength, and virtue. They are rainmakers and were the leaders of the Acoma people when they lived in the north. Anthropomorphic spirit rainmakers live in the west and are of the greatest importance in ceremonial. Mysterious spirits who dwell in the sunrise strengthen the weak and the sick. Most important of all, however, is Iatik, the great mother, the symbol of human life, but remote from the daily activities of her children. After death the individual goes back to her; but she is never pictured as human in form. The moon and stars are said by some to be spirits; while the clouds, especially the rain clouds, are important and prayers are said to them. Lightning is a symbol of power, and flints are called 'lightning stones'. Four rainmakers live at the cardinal points, each bringing a different type of wet weather. There are also hunting and medicine gods, and with them are San Estevan, Yoshthi, Dios (or God), and Christo. These are a survival of the Spanish conversion of the Acoma to Christianity. Dios is not considered well-disposed towards the Acoma, because he punishes after death, which the other gods never do. Prayer sticks are sometimes offered to him, but always accompanied by prayer sticks for the great mother, Iatik.

Insects attacking Hardwood Timbers in Great Britain.—The Department of Scientific and Industrial Research has recently issued a practical brochure entitled "A Survey of the Damage caused by Insects to Hardwood Timbers in Great Britain", by Dr. R. C. Fisher and Messrs. F. R. Cann and E. A. Parkin (Forest Products Res. Bull. No. 16. London: H.M.S.O. 2*s*. 6*d*. net). The losses incurred through attacks of beetles, mainly *Lyctus* powder-post beetles, by all branches of the hardwood timber trade, are increasing. The spread of native and imported species of *Lyctus* in timber stores is such that they now occur in almost every yard and workshop in which susceptible timbers such as oak, ash, walnut, and elm are used. The most reliable method of eliminating *Lyctus* infestation is by kiln sterilisation, in which the timber is heated up to a definite temperature in a moist atmosphere. The Forest Products Research Laboratory, which is responsible for this publication, considers that immediate steps should be taken to control the spread of *Lyctus* beetles in Great Britain. Co-operative action by all trades concerned would result in a widespread demand for kiln-sterilised wood, or wood otherwise free from attack. The bulletin contains the latest information on the *Lyctus* problem and recommendations to trades anxious to diminish losses from this source. It also gives information of the types of injury caused by other insects, and methods of distinguishing them. Unlike *Lyctus*, however, these do not survive the seasoning of the timbers.

Chromosome Numbers of the Genus Crocus.—The study of chromosome numbers is becoming of increasing interest. Mr. K. Mather (*Genetics*, vol. 26, No. 1) has made a comparison of the somatic chromosomes in many species of *Crocus* and finds every haploid number between 3 and 15 in this genus, which reproduces annually by forming corms. There is considerable differentiation between the chromosomes of a group, satellites and constrictions being present. There is also evidence of chromosome fragmentation in certain species. Although the haploid numbers form a continuous series, as in *Cyperus*, yet there is also evidence of polyploidy in certain species of *Crocus*, and some species and varieties are clones with an odd number of somatic chromosomes. Fusion of chromosomes may have been concerned in producing such low haploid numbers as 3 or 4. The genus also differs from *Crepis* in that no chromosome number is common to a large number of species. Measurements show that the total bulk of chromatin in the chromosomes may be from five to seven times as great in some species as in certain others with a higher chromosome number. In general, as the number of chromosomes increases there is a decrease in their length and an increase in their size differentiation. This work furnishes the beginning of an important study in chromosome phylogeny.

Maturity of Fruit.—An intensive investigation of the factors affecting the maturation of fruit is being

prosecuted by several members of the Long Ashton Fruit and Cider Institute. Dr. J. C. Hinton reviews the literature on the subject (Ann. Rep. of the Institute, 1931, pp. 40-53), and gives some interesting results of measurements made by a hardness tester. He finds that the rate of softening of later-picked fruit is greater than with earlier-picked produce. Apples from ringed trees and from grass orchards soften more slowly than fruit from cultivated fields, most probably because they have larger quantities of solids, and particularly carbohydrates. The same author reviews the problem from another angle in a later paper (pp. 54-67) of the same report. Extensive data as to the relative amounts of sucroses and hexoses are coupled with the results of starch tests at picking time, and lead to the general conclusion that fruits with a relatively favourable food supply ripen slower than those with a less favourable nutrition. This is, however, complicated by the special cases when potassium is deficient or when the tree is ringed or thinned, for the generalisation does not then hold. Messrs. J. C. Hinton, J. O. Jones, and F. C. Lewis have investigated the influence of position in the cluster on the quality of apples, pp. 68-76). Lateral fruits had more sucrose and lost weight quicker during storage than terminal fruits. Thinning to one fruit per cluster produced an increase in sucrose content of all fruits. Ash constituents were apparently not affected by thinning treatments.

Oxygen Intake of Living Tissues.—Dr. T. A. Bennett-Clarke (*Sci. Proc. Roy. Dublin Soc.*, vol. 20 (N.S.), No. 23, pp. 281-291) has described a method for recording automatically the oxygen intake of living tissues. The suggested method, based on that of Fernandes, embodies certain novel technical features which render it insensitive to changes in atmospheric pressure and include an automatic device for replacing the oxygen utilised by the tissue with oxygen electrolytically produced and introduced into the otherwise closed gas circuit. A specially constructed gas circulating pump which ensures a flow free from pulsations is described in some detail. Details of the methods used for carbon dioxide estimation are given. The methods have been applied (loc. cit. No. 23, pp. 293-299) to a study of the respiratory quotients of succulent plants. The changes with time of the oxygen absorption and carbon dioxide production of excised leaves of *Sedum prealtum* were determined and their theoretical significance discussed.

Thunderstorms and Penetrating Radiations.—Whereas C. T. R. Wilson has suggested that very penetrating radiations may be produced during thunderstorms, B. F. J. Schonland in 1930 reported that he had observed a screening effect due to thunderstorms on the ordinary fine weather penetrating radiation. As mentioned in a letter in NATURE of Sept. 10, p. 399, he has since confirmed this by further observations. Prof. G. B. Rizzo, of the Geophysical Institute, the University, Naples, writes to report a similar observation made on August 27, 1932, on Rocciamelone Mount, 3537 metres above sea level. During a very powerful thunderstorm, from $14^h\ 40^m$ until $18^h\ 20^m$ (M.E. mean time), there was a distinct diminution in the number of ion pairs formed per sec. per cm.^{3} inside an iron shield 5 cm. thick, placed in an alpine refuge, wooden roofed and covered with 1 mm. galvanised iron plate. The measurements, made with a Kolhörster electrometer (by Günther and Tegetmeyer) showed a reduction from 7·70 pairs before the storm, and values oscillating about 7·60 after the storm, to values of 7·05 during the storm.

The Velocities of the Ions Striking the Cathode of a Discharge Tube.—In the glow discharge an important part is played by the bombardment of the cathode by positive ions. This bombardment is an important mechanism in maintaining the supply of electrons for the discharge. The velocity distribution of the ions passing through a hole in the cathode has been roughly examined by the Doppler effect in spectral lines emitted by the canal rays, and by the intensity distribution in the J. J. Thomson parabolas, and some particles were found having velocities corresponding to nearly the full cathode fall of potential. Chaudri and Oliphant (*Proc. Roy. Soc.*, Sept.) describe experiments in which the beam of ions passes through a hole in the cathode into a space which is kept free from gas by a fast diffusion pump. The velocity analysis is then carried out by the electrostatic focusing method of Hughes and Rojanski. The velocity distribution curves show a maximum for a rather low energy (of the order of a quarter of the total cathode fall of potential)—with a sharp decrease at lower energies and a more gradual fall towards higher energies. Some ions were found with energies corresponding nearly to the full cathode fall, and it seems that these ions must go through the cathode dark space—about 20–100 mean free paths for molecules—without losing energy by collisions. The authors give a partial explanation of their results in terms of the ionisation efficiency of electrons and the consequent distribution of ionisation in the dark space. The peak in the velocity distribution they explain tentatively by invoking the exchange of charge (Kallmann and Rosen) between the fast ions and slowly moving gas atoms.

The Accommodation Coefficient for Helium on Tungsten.—In a paper in the September *Proceedings of the Royal Society* Jackson and Mott apply quantum mechanics to the problem of the collision between gas atoms and a solid surface. The latter is treated as an assembly of independent atoms which vibrate about a position of equilibrium. The energy of interaction of a gas and a solid atom is supposed to vary exponentially with the separation. The probabilities of energy transfers are calculated, and from these the thermal accommodation coefficient is deduced. The formula derived contains the 'characteristic temperature' of specific heat theory and a parameter characterising the law of interaction between gas and solid atoms. The formula fits well to Roberts's experimental curve connecting temperature and accommodation coefficient for helium on clean tungsten, when the one arbitrary parameter is adjusted for one temperature. The value of this parameter fits in with ordinary ideas of atomic dimensions.

Testing Strings of High-tension Insulators.—The high-voltage transmission cables used for the transmission of electric power are supported by 'strings' of insulators to the lattice towers. These strings have always to withstand very high electric pressures and sometimes owing to atmospheric and other disturbances a 'flash over' occurs and the string may be left in a damaged condition, one or more of the

insulators being punctured. To avoid interruption to the supply it is advisable to test the insulators at periods varying from six months to two years depending on special conditions. To the *Electrical Times* for Sept. 22 Mr. G. A. Robertson contributes a useful article on the new methods which are coming into use for detecting these faulty insulators. Some of the methods seem crude but are none the less effective. The 'buzz-stick' method, for example, consists of a long stick made of bakelite, an excellent insulator, with a pointed metallic object on the top shaped like a hay fork with an extra metallic prong at right angles to the two other prongs. If when holding the eight-foot stick at the insulated end the extra prong is made to touch the 'live' cable and then drawn slowly away, a buzzing noise is heard the loudness of which depends on the rate the fork is moved away and on the voltage of supply. The prong is then applied to the caps of the various insulators in turn and drawn away at the same rate. The sounds heard should vary according to the normal distribution of potential along the string. The next test is to bridge each insulator in turn by the two prongs of the fork. When they are sound, short snappy sparks are produced, the intensities varying with the potential distribution. When an insulator has been perforated no spark occurs and so it is detected.

North American Game Birds.—The ninth of the valuable series of bulletins on the life-histories of North American birds, published by the United States National Museum, concerns the gallinaceous birds (orders, Galliformes and Columbiformes), and on that account is of more than usual interest to the general reader (*U.S. Nat. Mus. Bull.*, 162). It is the first of the series in which any considerable number of subspecies had to be dealt with, but technical descriptions are reduced to a minimum, and the author, Arthur Cleveland Bent, has made full use of historical data and of the observations of habits made by correspondents. Some notion of the scale upon which the volume is written will be gathered from the fact that 24 pages are devoted to the extinct passenger pigeon, and almost 16 to the heath hen, one among the first of the American birds to be mentioned in the writings of the early colonists, and now apparently represented only by a single aged male individual living in Martha's Vineyard Island, Mass.

Astronomical Topics

Theories of the Evolution of Binary Stars.—*Revue Scientifique* for July 23 contains a discussion on this subject by Dr. P. Baize. He first discusses the capture theory, which imagines the chance approach of the two stars, constrained either by collision with each other or with secondary bodies of their systems to remain in company; it is easily shown that such collisions or appulses would be too rare to explain the immense number of binaries. The theory of neighbouring nuclei in a nebula, favoured by Sir James Jeans to explain the binaries of long period, does not meet with much favour from Dr. Baize. He suggests as an alternative an explosive expulsion from the primary, and refers in support of this view to the companion bodies of Nova Pictoris. But the products of such explosions would either recede indefinitely or would intersect the parent star on their return. Perturbations might prevent actual impact, but it would be a long step from such perilous near approaches to the safe and stable orbits of most of the known binaries. The theory of fission of the primary through rapid rotation, favoured by many cosmogonists to explain the spectroscopic binaries and other close pairs, is taken by Dr. Baize as the general mode of origin of most binaries. He is aware of the immense gap that intervenes between the initial small circular orbits and the large elongated ones, with periods of centuries, of many visual binaries; but he conjectures that loss of mass through radiation, and possible disturbances by passing stars, might bring this about in the billions of years (he says trillions, but he means British billions) which he postulates for the life of the stars.

Exception must be taken to a sentence of the article: "Les étoiles du type 61 Cygni dont le mouvement relatif s'exécute en ligne droite. . . ." It was shown first by Peters, then by T. Lewis, lastly by A. Fletcher (*Mon. Not. Roy. Astro. Soc.*, Dec. 1931), that the motion of 61 Cygni is not rectilinear, but in an ellipse with a period in the neighbourhood of seven centuries.

Report of the Cape Observatory for 1931.—This report contains an account of much important work; that relating to the observations of Eros is of special interest. The unexpectedly large deviation of Eros from its predicted place necessitated the selection of some new stars of reference; stars from both the old and new lists have been well observed at the Cape. Stars in the zone $-30°$ to $-35°$ are being observed as reference stars for the photographs taken of this zone; a new list has been prepared of stars down to mag. 7·5 between the equator and $-30°$. 475 plates of Eros were obtained with the Victoria telescope and 678 plates with the astrographic one; the latter are fairly equally divided between large easterly hour-angles, small hour-angles, and large westerly ones. Plates were also taken with a wire grating, to detect stars of outstanding colour-index, and others for obtaining positions of the reference stars. Eros was photographed until May 1931, to provide material for Prof. Gustav Witt, who is revising the orbit.

Observations of the outer planets with the heliometer were continued; the results will be published when revised positions of the comparison stars are available.

The report contains a note on changes in the spectrum of Nova Pictoris, of which a spectrogram was taken at the Union Observatory, Johannesburg, in February 1931. Two lines of unknown origin, at 6088 and 5722, were the strongest; then followed the line $H\alpha$, and that at 4686, due to ionised helium; there was no trace of the nebular emissions, N_1 and N_2, which were present, but weak, in 1928. The year 1931 was a dry one at the Cape, the rainfall being 19·09 inches, which is 5·28 inches below normal; the mean temperature was 63·8° F., which is 1·4° above normal.

Minor Planets.—Circular No. 653 of the Berlin Rechen Institut assigns permanent numbers to fifteen new planets discovered between 1927 and 1932; three of these proved to be identical with planets observed, but not numbered, in earlier years. The new numbers run from 1209 to 1223. The interesting planet discovered by M. Delporte at Uccle last March, which comes nearer to the earth than Eros, receives the number 1221 and the name *Amor*; this was doubtless chosen as suitable for a companion of Eros.

Conference of the Association of Special Libraries and Information Bureaux

THE ninth annual Conference of the Association of Special Libraries and Information Bureaux, which was held at Somerville College, Oxford, on Sept. 23–26, opened and closed on a note echoed from the British Association meetings at York. In an opening address to the Conference on Sept. 23, on "Science and the Humanities", Prof. J. L. Myres directed attention to three characteristics of our own age, in the abundance of information and of working tools or instruments as well as of those who use them, linked up with increasing opportunities of use and the growing complexities of organisation directed to make both more accessible, and suggested that the depression which accompanies this superabundance of means is possibly no temporary depression. The leisure state may well be upon us and it is difficult to predict what the new order will be. All that can be said is that the situation must be met with new ideas and new projects, and Prof. Miles Walker's address at the British Association meeting was essentially a challenge to the present order and to the general outlook. With this the Association of Special Libraries and Information Bureaux is concerned in the provision of information relating both to accurate knowledge of the world and to the training necessary to make people competent to live. Sir Alfred Ewing's presidential address at the York meeting of the British Association likewise issued a challenge to modern politics, economics and systems of education and raised the whole question of the relative value of science and the humanities both in society and in the preparation of people for its privileges.

Prof. Myres pointed out that while the scientific method makes its chief contribution to human welfare in the assistance it gives in the observation and interpretation of experience, scientific achievement is at once impeded by the absence of moral qualities and æsthetic or artistic taste, and the humanities or human sciences such as human biology, psychology, statistical economics, make an equally important contribution in training human qualities, and the activities of the individual. The development of self-consciousness and self-control is an important aspect in social relations, and full use of information presumes the discernment of individuality in ourselves as in others. Accordingly moral, political, economic and social methods have a geographical or distributional aspect as well as a historical aspect. This, together with the distributional aspects of the systematic sciences, which only become directly applied to life when local or temporal conditions are involved, cuts right across the traditional view of the humanities and even raises doubts as to whether any real distinction is possible between the human and the pure sciences. Prof. Myres suggested that the teaching of a systematic science should be humanised by paying more attention to its historical growth and regional application, and also that the teaching of the humanities might be clarified and intensified by a firmer distinction between their systematic aspect and those historical and regional reconstructions which alone can set the civilisations of the present in an intelligible perspective.

The same vigorous and refreshing outlook characterised the closing address to the Conference, in which, pointing out that the present depression is sapping moral as well as material resources, Mr. F. W. Pethick-Lawrence emphasised the importance of rational thinking on the situation and of discarding the old method of trial and error. Financial muddling is directly responsible for the crisis, and the way out of our difficulties lies in the intelligent use of accurate information, in treating finance not as an end in itself but as the handmaid of politics.

Comparing the present with previous Conferences, it is evident that the industrial representation is gaining strength and that despite its financial difficulties, the Association is steadily proving its worth and demonstrating the value of the co-operation which it has already established between special libraries and information bureaux. It is clear from discussions like that opened by Dr. S. C. Bradford on "Systematic Subject Indexes to Periodical Volumes" that there is still plenty of room for further co-operation. The intensely individualistic point of view of some special librarians or heads of information bureaux which was evidenced in this discussion probably deserves some of the strictures recently uttered against the expert and the specialist, and has sometimes led them to overlook practical advantages in the decimal classification. On the other hand, those most interested in securing the adoption of the universal decimal classification have sometimes failed to realise the practical and even financial difficulties which at present beset the application of the classification in certain sections of industry. It is perhaps a little unfortunate that the Association devoted so much time at its conferences to a subject on which there is a strong cleavage of opinion, particularly as, with the growth of co-operation, the practical advantages of the decimal classification for many purposes may be more fully appreciated.

The discussion centring round the decimal classification was somewhat marred by the absence of an impartial chairman, but if any criticism is offered of the following discussion on the establishment and operation of an information service, it is that the joint paper circulated in advance to the Conference was treated at such length by the four joint authors that little time was left for discussion. This was evidently felt by the meeting, for a resolution was passed and adopted at the final session of the Conference, asking for a similar discussion on particular aspects of information services, especially in regard to co-operation, to be arranged at future conferences.

The discussion was opened by Mr. A. F. Ridley, of the British Non-Ferrous Metals Research Association, who stressed the advantages of an efficient information service in handling a far greater body of knowledge than could possibly be handled haphazard by individuals. Such a service, while not relieving individual members of the organisation from the duty of reading and digesting all information of importance to their work, assists them by selecting for them to read the information bearing on their special work. This work is educative as well as informative, inducing members of the organisation to make better use of the facilities offered. Special emphasis was placed on the selection of staff, as although much of the work is routine, it must never be allowed to become too much so. A very real part of the business of an information service is to safeguard the organisation for which it works from

becoming hidebound with tradition. Initiative is of high importance, and the shortness of the time-lag between publication of information and its being brought to the notice of the individual needing it is largely a matter of adequate library, technical and clerical staff.

Miss E. W. Parker, of the Mond Nickel Co. Ltd., stressed the value of external literature surveys conducted outside the library as a means of supplementing information received in the library. Much valuable advance information can be obtained by co-operation and by contact with technical and scientific personnel all over the world. As regards bibliographical work, Miss Parker suggested that it is important to produce bibliographies in advance of the demand, and stressed the importance of attention to detail in such matters as well as in dealing with inquiries. It is doubtful whether any inaccuracies in such work can be described as minor. Mr. E. J. Carter emphasised aspects of the information service maintained by the Royal Institute of British Architects, stressing particularly the importance of maintaining a full service of journals and books inside the library and the value of propaganda regarding the services offered. Mr. T. M. Herbert described the information service recently developed as part of the research organisation of the London Midland and Scottish Railway.

An animated discussion, opened by Mr. J. P. Lamb, chief librarian to the City of Sheffield, with a paper entitled "The Public Library as an Aid to Industry and Research" and by Mr. B. M. Headicar with a paper, "Research: Where the Library and Librarian come in", focused attention on the general neglect of the municipal library by industry. Mr. Lamb referred to the possibilities of co-operation between the public libraries and special libraries in regard to co-ordination of purchases of books and the pooling of periodicals and storage space. In the course of discussion, Mr. Lamb directed attention to the changed conditions under which the reference library now operates and the necessity for some elasticity in adapting its former rigid procedure regarding the loan and exchange of books. Where local conditions permit rapid and easy book exchange a very useful field of co-operation between industrial and municipal libraries exists and a promising tendency is that towards the development of a pool of technical and specialised works between the strictly reference library and the general library.

Prof. M. Greenwood delivered a delightful paper on the "History and Sources of Official Vital Statistics" in which a keen sense of humour enabled him to make an apparently uninteresting theme eloquent and to convey to others something of the fascination the subject has for the expert as well as of the difficulties and pitfalls which beset those attempting to compare vital statistics or to base conclusions on them.

One of the most important discussions, to which very little time was allotted, however, was that initiated by Mr. A. A. Eldridge's report on the A.S.L.I.B. inquiry into technical and scientific abstracting. This inquiry was conducted by a small committee of which Mr. A. A. Eldridge was chairman and was the direct outcome of the informal conference convened by Mr. H. T. Tizard last year at the Imperial College of Science and Technology. The report presented by Mr. A. A. Eldridge was purely preliminary and outlined the general trend of the replies received to the questionnnaire. Some fifty replies had been received covering nearly all the important abstracting agencies in Great Britain, including research associations and imperial bureaux, the Department of Scientific and Industrial Research, the Royal Photographic Society, the Textile Institute, *British Medical Journal*, Bureau of Chemical Abstracts, Institution of Civil Engineers and various industrial firms like the British Aluminium Co. Ltd., J. Lyons and Co. Ltd., Imperial Chemical Industries Ltd., Metropolitan-Vickers Electrical Co., Ltd.

The report directs attention to the opportunity for co-operation in the purchase or examination of journals of secondary interest and distinguishes between overlap in preparation and unavoidable overlap in publication. The replies received in answer to the questions regarding the qualifications for abstractors and their selection should provide the Association with a valuable analysis of experience as a basis for useful suggestions in response to definite requests for help. Divergent opinions were expressed as to the value of authors' summaries where provided, and opinion was expressed in the discussion on the report that abstracts must be written from the point of view of the user for whom they are intended. This is particularly true of the industrial abstracting services, but such services are frequently run deliberately to supplement and not to replace the work of agencies like the Bureau of Chemical Abstracts and the view that abstracts are best contributed by specialists in a particular field finds little support in industry. The discussion suggested that full time abstractors who are generally familiar with the subject and its principal complexities are regarded as most satisfactory for the special libraries or information bureaux. Attention was also directed to the desirability of uniform practice in regard to the abbreviations used for journal references, etc., and the transliteration of names in non-Latin scripts, as well as to the difficulties in the way of co-operation presented by the introduction of abbreviations into the text of abstracts.

At the annual meeting, discussion on the report and on what members want of A.S.L.I.B., initiated by Mr. H. Robinson of the Textile Institute indicated a very lively appreciation of the valuable work which the Association is carrying out and the wide and useful field of co-operation open to it. Sir Charles Sherrington was elected president of the Association in succession to Mr. H. T. Tizard.

A Census of Summer Thunderstorms

THE first annual report of the Thunderstorm Census Organisation, Langley Terrace, Huddersfield, deals statistically with the records obtained, largely with the aid of private observers, during the six summer months April–September of 1931. It is an amateur enterprise conducted by Mr. S. Morris Bower as a sequel to a similar investigation carried on during a long period by Mr. C. J. P. Cave into the occurrence of thunderstorms in winter. The British Rainfall Organization, which is now part of the organisation of the Meteorological Office, Air Ministry, no doubt began in much the same way to supply information about one meteorological element with a greater degree of detail than could possibly be done without the aid of voluntary observers. The demand for such detailed information about

rainfall on the part of engineers occupied with water supply is considerable and fully justifies a permanent organisation of that kind; whether the same will be found in the case of thunderstorms as a result of electrical developments, wireless transmission, and aviation, remains to be seen.

The response to this enterprise has been very good for it is stated in the foreword to this report that 966 voluntary observers and organisations have contributed to it. The only criticism that suggests itself is that the working up of the statistical material does not appear to promise any notable advance in our knowledge of the conditions favourable for the development of thunderstorms, or of their life history. Great accumulations of statistical information of this kind abound in meteorology, but it only too often happens that nobody comes forward to extract new knowledge from them.

Nothing in the way of a generalisation is suggested by this report except that the regions of maximum frequency of winter thunderstorms—the western coasts of Scotland and Ireland—are roughly those of minimum frequency of summer storms. This is not new knowledge; it has been recognised with the aid of a comparatively moderate number of regular official observing stations, and the explanation is furnished by ordinary synoptic meteorology, when due attention is paid to the possible ways in which atmospheric instability can arise at the two seasons. It seems reasonable to suppose that real advance will necessitate a study of selected portions of this detailed statistical information on correspondingly detailed synoptic lines in the endeavour to trace the physical processes that accompany the development and decay of individual storms or systems of storms.

Mathematical and Experimental Evidence for the Existence of a Central Intellective Factor*

By DR. WILLIAM BROWN

If a number of sufficiently dissimilar mental tests of intellective ability be applied to a group of individuals and correlation coefficients calculated, it is found that these correlation coefficients are related to one another in such a way that for any four (or *tetrad*) of them the following relation holds good within the limits of random sampling:

$$r_{ap}\, r_{bq} - r_{aq}\, r_{bp} = 0;$$

and similarly with other arrangements of these four coefficients. We owe both the discovery of fact and the devising of the tetrad criterion to Prof. C. Spearman.

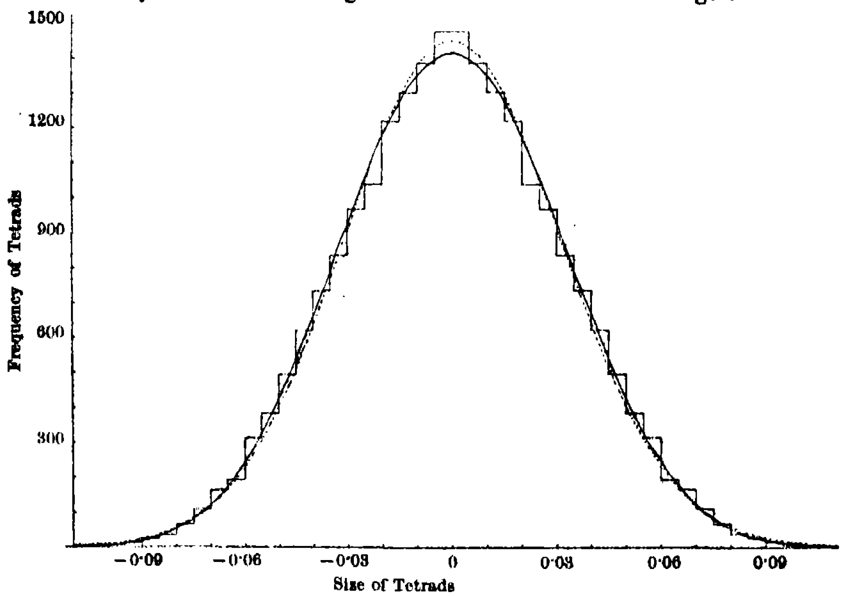

FIG. 1. Frequency distribution of tetrad differences. Best-fitting curve (Type IIa Pearson Curve) ———. Best-fitting Probability Curve ....

The inference drawn from this is that the abilities measured by the mental tests are divisible into two factors each, one being common to all (the general factor, g), while the other is in each case specific and independent (the specific factor, s).[1]

The method of applying the tetrad criterion is to draw up a frequency distribution of all the possible tetrad differences derivable from the table of correlation coefficients ($6 \times {}^nC_4$ in number, where n is the number of mental tests correlated with one another), and to compare its standard deviation with the 'theoretical' standard deviation of a purely chance distribution of such tetrad differences. A formula for the latter has been calculated by Spearman and Holzinger.

I have re-tested my earlier correlation results of twenty to twenty-three years back[2] by this criterion, and find that, so far as they go, they do support Spearman's two-factor theory. But a statistically adequate proof of the theory needs a large random sample of cases (several hundreds) and, especially, a large number of not too similar mental tests of intellectual ability—much larger than those applied in any research up to the present date.[3]

To fulfil these conditions, I have organised a research during the past year with the help of Prof. Spearman and Dr. W. Stephenson of University College, London. Dr. Stephenson has devised a series of twenty tests of apparently non-overlapping intellective ability, selected not *a priori* but after much preliminary trial, which received the approval of Prof. Spearman, and has applied them for me to 300 boys, aged 10½–11 years, drawn from twelve elementary schools of the L.C.C., forming a homogeneous random 'sample' of adequate size for statistical purposes. The total number of positive tetrad differences is 14,535 (and there is an equal number of negative tetrad differences, of course). It has since been found necessary to reject one of the tests and one of the correlation coefficients. There remain 11,356

* Summary of a paper read on Aug. 24 to the Tenth International Congress of Psychology at Copenhagen.

positive tetrads (and an equal number of negative ones) which form a smooth frequency curve, the mathematical properties of which I am now working out.

I have found that the best-fitting frequency-curve is a Type IIa Pearson curve, with equation

$$y = 1412\left(1 - \frac{x^2}{1188}\right)^{13 \cdot 669} \text{ [unit of grouping} = 0 \cdot 005]$$

The curve is platykurtic, with $\beta_2 = 2 \cdot 81446$. (For a 'probability' curve, $\beta_2 = 3$). $\chi^2 = 20 \cdot 69494$ (for 21 groups), and therefore $P = 0 \cdot 41537$,—a good fit. The standard deviation, $\sigma_t = 0 \cdot 031289$.

If we compare this with the 'theoretical' Spearman-Holzinger value[4], $\overline{\sigma}_t = 0 \cdot 02827 \pm 0 \cdot 002586$, we find an excess of $0 \cdot 003019$, which is $1 \cdot 167$ times the probable error. This means that the odds are about 4 to 3 against such a deviation,—a good correspondence of observation with theory.

The best-fitting *probability curve* to the distribution is

$$y = 1448 \, e^{-x^2/78 \cdot 32}$$

This is far less good a fit than the Type IIa Pearson curve above-mentioned, since for it $\chi^2 = 39 \cdot 21517$, and therefore $P = 0 \cdot 0114809$,—a poor fit.

The small size of P is partly due to the large number (21) of groups in each half of the frequency-distribution. Actually both curves appear to fit the distribution closely, when superposed upon it, and the superiority of the Type IIa curve only becomes visually apparent in a large-scale drawing, such as would be too large to reproduce here.

University and Educational Intelligence

BIRMINGHAM.—Prof. W. Stiles has been elected dean of the Faculty of Science to succeed Prof. S. W. J. Smith whose term of office has expired.

OXFORD.—Dr. F. Homes Dudden, Master of Pembroke College, delivered on Oct. 5 his valedictory address as retiring vice-chancellor. In it, after paying tribute to the memory of the late Dr. G. Claridge Druce, of whom he spoke as the greatest English field botanist of his generation, he extended the welcome of the University to Prof. Plaskett, the new Savilian professor of astronomy. He announced that the extension of the Radcliffe Science Library would be taken in hand at once, though the additional space thus secured would at first be used to relieve congestion in the main Bodleian building. Among benefactions he mentioned the gift of £1000 from Prof. J. M. Baldwin for the capital endowment of the Edward Bagnall Poulton Fund ; and as recent interesting developments he enumerated the experimental establishment of a bureau for the prosecution of research on the ecology and population problems of wild animals, and the proposed establishment of an Institute of Ornithology to collect and co-ordinate information concerning the numbers, distribution, and habits of British birds.

ON November 4, at 8 P.M., Mr. H. Ramsbotham, Parliamentary Secretary to the Board of Education, will open the building extension of the Chelsea Polytechnic, Manresa Road, London, S.W.3, and distribute diplomas and certificates to students.

THE Trustees under the will of the late Viscount Leverhulme have instituted a number of post-graduate studentships in chemical engineering. These studentships, which are of the annual value of £250 each, are tenable at the Ramsay Memorial Laboratory of Chemical Engineering, University College, London. They are open to graduates in chemistry or engineering who also have an adequate acquaintance, gained by employment or otherwise, with factory or business conditions. The holders of the studentships may, at the discretion of the Ramsay professor of chemical engineering, either follow the ordinary course of study, leading to the College diploma in chemical engineering, or a special course of study in that subject, or carry out original research work. It is particularly appropriate that these studentships should be associated with the memory of Lord Leverhulme, since chemical engineering research and practice have always played a very large part in promoting the development and success of the great industrial organisation which he founded. Two studentships are to be awarded immediately. Applications for these should be addressed to the Secretary, University College, Gower Street, London, W.C.1.

THE London County Council's programme of lectures and classes for teachers includes under the headings of Science and Domestic and Health Subjects items which should enable teachers to make good some of the alleged deficiencies in present practice. A course of lectures and demonstrations by Mr. F. J. Pearson at the Institute of Education in "General Science for Senior Pupils", will direct attention to the advantage of framing science syllabuses on a wider basis than that traditionally employed. Courses of lecture-demonstrations by Prof. J. R. Partington at East London College, in "The Chemistry of Daily Life", and by Prof. Chas. R. Darling at the Borough Polytechnic, in "Physical Science in the Modern Home", will illustrate the application of the principles of science and scientific knowledge to vocational and other useful purposes, and link up work in the laboratory with work in the kitchen. Biology presents special difficulties as a practical school subject, especially in urban schools. Assistance in overcoming them will be the aim of a course of ten lectures by Miss von Wyss, beginning next January, at the Institute of Education. Food and dietetics will be dealt with in a course of lectures by Prof. Winifred Cullis, beginning in February.

RURAL schools in the United States of America have for many years presented peculiar problems of great difficulty and importance. Their importance is apparent in view of the fact that schools in rural districts (population under 2500) have an enrolment of nearly eleven million children and are staffed by four hundred thousand teachers. As schools have to a large extent been administered as a local district affair, and as wealth has been largely concentrated in urban districts, the schools in the rural districts have suffered from lack of financial support comparable with that enjoyed by city schools. The backward condition of large numbers of them has been known in a general way, but few research agencies have interested them-

selves in this field. A notable contribution to knowledge of the subject has been published by the United States Office of Education in the form of a pamphlet (*Bulletin* No. 3 of 1932), entitled "Status of Teachers and Principals Employed in the Rural Schools". Within rather wide limits, school boards of most rural communities still hire whom they please, agree among themselves concerning professional standards, and bargain with the candidates for the lowest possible salary rates. It appears that the average annual stipend is 926 dollars. Nearly forty per cent of the entire number of teachers are employed in one-room schools. Nearly one-fourth of this group are twenty years of age or younger, and about four per cent are not more than eighteen. The most extreme status problem, the report says, is presented by the negro teachers of one-room schools, upwards of eighteen thousand in number, who receive, on an average, only 314 dollars a year, and have received an education equal to only about 2½ years above the elementary school standard.

Calendar of Geographical Exploration

Oct. 19, 1920.—Flora and Rivers of South-East Asia

F. Kingdon Ward reached the Tra-mu-tang and the marble gorge of the Salween, just above which the glacier-fed torrent from the Gomba La enters. The torrent was followed to the Salween-Irrawaddy divide. On this journey Kingdon Ward verified the conclusion that the Mekong-Salween divide up to the 28th parallel forms roughly the boundary between a Chinese flora to the east and an Indo-Malayan to the west. He also made some observations on the deglaciation and morphology of the region. Kingdon Ward has continued his explorations in the mountain masses of south-west China and its borders and has combined botanical work with geographical discovery.

Oct. 21, 1883.—Greely in the Arctic

Lieut. A. W. Greely and his party were obliged to winter at Cape Sabine, their third winter without supplies. A few depots were found which had been left by Sir George Nares and W. M. Beebe, but all stores were exhausted before the spring. When the sun reappeared in 1884, some of the party died of starvation and the relieving steamers did not reach Cape Sabine until June 22. Greely and his party were found almost at the point of death, but with their scientific instruments in order and with their great collections of specimens intact. Greely's party had been conveyed to Lady Franklin Bay in 1881 as the American contingent of the series of circumpolar stations arranged for at an international polar conference held in Hamburg in 1879. A relief ship should have reached the party in 1881, but failed to do so until 1884, with lamentable consequences for the unfortunate party, which in spite of great misery and suffering, heroically continued its scientific work during the whole of the period. Much geographical survey work was carried out, especially in Grinnell Land and along the north coast of Greenland.

Oct. 21, 1928.—The Alai-Pamir Expedition

The Alai-Pamir expedition returned to Osh, whence it had started on June 19. It was a joint expedition organised by the Notgemeinschaft der Deutschen Wissenschaft in Berlin and the U.S.S.R. Academy of Sciences in Leningrad, in charge of W. Rickmers Rickmers, who had in 1913 conducted an expedition in the same region. The results of this work are not yet published in full, but much new topographical detail is already available. The scientific staff of the expedition collected much meteorological, ethnological and biological data.

Societies and Academies

Paris

Academy of Sciences, Sept. 5 (vol. 195, pp. 505–524).—L. Mangin: Notice on Roland Thaxter.—Gr. C. Moisil: The sudden breaks of probability in stochastic evolutions.—Jean Mirguet: The paratingent of a point ensemble.—Benjamin Meisel: A property of the strain in a plane problem of the theory of elasticity.—P. F. Papcovitch: The general solution of the fundamental differential equations of elasticity, expressed by three harmonic functions.—Léon Auger: The movements of pulsating reeds in organ pipes. An experimental study of the movements of the tongue of a vibrating reed, recorded photographically, with varying wind pressure.—René Hardy and Bertrand-Lepaute: A direct reading stroboscopic radio-compass.—A. da Silveira: The Raman effect in saline solutions.—C. Gaudefroy: Correction and addition to the description of equiline and folliculine.

Geneva

Society of Physics and Natural History, July 7.—E. Cherbuliez and Fr. Meyer: New researches on the fractionation of casein. According to recent results, casein contains at least two different constituents, one called α, insoluble in dilute ammonium chloride, whilst the other, β, is soluble in this solvent. The authors have proved that the β part itself consists of at least two substances, one precipitable in the saline solution at $pH = 3 \cdot 6$ and constituting the greater part of the soluble fraction (γ), the other remaining in solution under these conditions and precipitable by acetone (δ). The proportions by weight of the three fractions in the casein have been approximately determined: α, 65–70 per cent; γ, about 30 per cent; δ, 2 per cent. Moreover, these proportions appear to be variable. The three constituents have been also characterised by their percentage composition, especially by differences in sulphur and phosphorus, and their varying proportion of tryptophane.—E. Cherbuliez and Mme. J. Stephani-Cherbuliez. The influence of the intramuscular introduction of oil on the proportion of lipases in the blood serum. As the result of work on antituberculous chemitherapy by means of oil solutions of compounds of copper, the authors have taken up the old problem of the influence of the introduction of foreign fats on the lipolytic power of the organism. In tests made on man, extending over several weeks, they have proved that intramuscular injections of olive oil and of solutions of drugs in this oil do not appreciably modify the proportion of lipases in the serum. Further work should show if the lipolytic powers, especially the leucocytes, undergo modification in the course of the treatments indicated.—W. Bader: The synthesis in two stages of acetic acid from water gas. Methanol is first prepared using vitreous oxide or sulphide catalysts, in which the spacing of the active points is not the same as in crystalline cata-

lysts. Then the methanol as methyl phosphate is combined with carbon monoxide at 300°–320°C. and under a pressure of 100–200 atmospheres. The catalyst is a cuprous-phosphoric complex dissolved in the acid. Only acetic acid and methyl acetate are formed in this reaction.—**A. A. Bron** and **E. Briner**: Researches on the catalytic dehydration of some phenols. The authors have dehydrated a certain number of phenols, and specify the action exerted by certain chemical groups on the tendency to dehydration.—**P. Bolle** and **E. Briner**: The chemical activity of nitric acid in solution. The results deduced from the study of reactions of nitration and of absorption of nitric oxide by nitric acid show that these reactions are due to the non-dissociated fraction of the nitric acid.—**E. Briner** and **H. Biedermann**: Peculiarities of the chemical reactivity of ozone in the absence of oxygen. By replacing oxygen by nitrogen as a diluent of ozone, it has been recognised that the oxidising power of ozone on benzaldehyde is reduced to one atom of fixed oxygen for each molecule of ozone consumed. —**A. J. Weigle** and **R. Luthi**: The abnormal dispersion of amyl alcohol for short wave-lengths. The dielectric constant of a solution of amyl alcohol in a very viscous oil (Shell *BL*3) has been measured at − 10°C. for waves varying between 334 and 2·8 metres wave-length. The dielectric constant diminishes since the dipoles of amyl alcohol no longer take up a definite position in the electric field. Moreover, this decrease does not correspond with that predicted by the Debye theory. These experiments give interesting information on the structure of liquids.—**J. Weigle** and **H. Saini**: A new apparatus for the exact determination of the dimensions of crystalline networks. An apparatus based on the Seemann-Bohlin principle has been constructed by the authors. Making use of interferences of high order, the crystal dimensions can be measured with an accuracy of about 1 in 100,000. This apparatus can be used for the determination of coefficients of thermal expansion of crystal networks.—**W. H. Schopfer**: The supposed vitamin action of some amines. The author's experiments, made with histamine, tyramine, glucosamine, hordenine, betaine, choline, ethylamine and ethylenediamine show that it is impossible to attribute the slightest vitamin action to these substances.

Rome

Royal National Academy of the Lincei, April 17.—**L. Cambi** and **L. Szegö**: Sulpho-salts of copper and iron. In its magnetic behaviour, the sulpho-salt $KFeS_2$ approximates to pyrites, ferrous sulphide, and many complex ferrous salts, whereas the sulpho-salts $K_mFeCu_nS_p$ recall, on one hand, pyrrhotine, and, on the other, those ferric sulpho-salts in which the iron present is assumed to have the structure of the ferric ion. The tendency to assume states approaching the diamagnetic state at low temperatures is observed with the paramagnetic sulpho-salts of iron. The sulpho-salts now under consideration are diamagnetic, as also are the copper sulphides.—**Enea Bortolotti**: Deformations of higher species and systems of forms for a V_m in R_n.—**E. Gugino**: The geodetic curvature of the lines of a Riemannian space of *n* dimensions. —**U. Broggi**: A generalisation of the developments in series of determinant functions.—**Maria Cibrario**: The reduction to canonical form of the linear equations to the partial derivatives of the second order of mixed type.—**T. Viola**: Functions of continuous limited variation towards the right.—**A. Masotti**: A theorem of unicity relating to Poisson's equation. —**M. Zeuli**: A generalisation of the centre of the osculatrix sphere.—**N. Cioranescu**: The determination of a harmonic function by the initial global conditions. —**Ruy Luis Gomes**: The limits of the normal derivative of a simple layer potential.—**G. Colonnetti**: Influence of the shearing force on the deflection of a beam. (2) Further proof of the fact that the shearing force influences the deflection of an inflected beam is obtained by consideration of the case of a lattice girder with parallel top and bottom members.—**F. Conforto**: Impulses in isotropic elastic bodies.—**D. Graffi**: Adiabatic invariants as a method of approximate integration of differential equations.—**G. Krall**: Distant limits of the motion of a planetary system.—**U. Barbieri**: Astronomico-geodetic station on Bric Torniola, July 1928.—**G. Viola**: The periodicity of the mean annual temperature in relation to that of sunspots. For Naples, Rome, and Gaeta, the period of variability of the mean temperature is about one-half of the frequency period of sunspots. These results are at variance with those of Köppen, according to whom the mean temperature curve exhibits a course opposite to that of the sunspot curve.—**Joan Y. Placinteanu**: The equilibrium between matter and radiant energy. In studying the radiation of the stars, Eddington advanced the hypothesis that this radiation is always accompanied by variation in the total mass of the star, the atoms of matter undergoing transformation into particles of radiant energy, and Stern deduced a formula for calculating, for the case of thermodynamic equilibrium, the number of particles per c.c. The author now considers the conditions when photons are present and shows that Stern's formula does not then apply.—**D. Bocciarelli**: Radioactivity of potassium. Occhialini's method of magnetic analysis, devised for studying the β-radiation of rubidium, has been used for investigating the still feebler radioactivity of potassium.—**T. Carpanese**: Granite, vesuvian, ilmenite, and titanite from Monte Rosso di Verra (Monte Rosa group).

Sydney

Linnean Society of New South Wales, May 25.—**H. J. Carter**: New Guinea and Australian Coleoptera. The paper contains descriptions of twenty-two species as new, in the families Georyssidæ (1 species), Buprestidæ (4), Tenebrionidæ (9), Cistelidæ (3), and Cerambycidæ (5).—**J. G. Churchward**: Inheritance of resistance to bunt, *Tilletia tritici* (Bjerk.) Winter, and other characters in certain crosses of 'Florence' wheat. 'Florence' was crossed with four susceptible commercial Australian varieties of wheat, each cross giving a similar result. A graph representing distribution of F_3 families in 5 per cent classes for bunt infection shows a trimodal curve indicating a single factor difference for bunt resistance. Experimental results of the crosses are given, and also results of observations on the occurrence of grass clumps and the inheritance of chaff colour.—**G. A. Currie**: Some notes on the biology and morphology of the immature stages of *Harpobittacus tillyardi*. The larvæ and pupæ of *Harpobittacus tillyardi* E.P. are described for the first time. Notes on the biology of the insect are given and, as the larvæ of Australian Bittacidæ have hitherto been unknown, their feeding and other habits are described.

Royal Society of New South Wales, June 1.—**W. H. Love**: The mitotic activity of normal and malignant tissues and its modification by X-rays. This study is made from the biological, physical, and mathematical points of view. A theory of the occurrence of mitosis in normal tissue cultures (fibroblasts), and in Jensen's rat sarcoma, is developed and applied to several aspects of the problem of cell division. The quantita-

tive modifications produced by X-rays in the mitotic activity of these tissues are then studied experimentally and analytically. Within certain limits, the experimental results are in good agreement with the predictions of analysis. Outside these limits there is, in some experiments, a marked divergence between the two. The significance of this divergence is considered, and an explanation, supported by experimental evidence that seems conclusive, is advanced.—J. C. Earl and N. F. Hall: The chemical changes involved in the formation of aminoazo-compounds (1). By examining the volume-temperature curves of methanol solutions containing amine hydrochlorides and sodium nitrite, an indication has been obtained of an intramolecular rearrangement of amine nitrite to an intermediate compound prior to the formation of diazocompound or nitrosamine. When the solution is kept neutral by employing equimolecular proportions of amine hydrochloride and sodium nitrite, the change does not take place, nor, in the case of aniline, does the solution show any coupling with alkaline β-naphthol. Addition of a small quantity of acid to such a mixture brings about the formation of diazocompound as shown by the coupling reaction with β-naphthol (*cf.* Wallach, *Annalen*, **257**, 319).—Thelma M. Reynolds: Note on the action of titanium tetrachloride on tetracetyl-β-*d*-glucosido-glycollic ester. Tetracetyl-β-*d*-glucosido-glycollic ester (Fischer and Helferich, *Annalen*, **383**, 81; 1911) reacts with titanium tetrachloride in the same manner as the fully acetylated sugars (Pacsu, *Ber.*, **61**, 1508; 1928) giving acetochloroglucose, whereas the β-glucosides previously studied (Pacsu, *loc. cit.*; *J. Amer. Chem. Soc.*, **52**, 2563; 1930) were rearranged into the corresponding α-glucosides.

Forthcoming Events

MONDAY, Oct. 17

King's College, London.—Prof. Claude F. A. Schaeffer: "The Excavations at Ras Shamra in Syria—the Results of the Four First Expeditions, 1929–32", at 5.30 (succeeding lectures on Oct. 20 and 21).

London School of Hygiene and Tropical Medicine (Heath Clark Lectures).—Prof. Carl Prausnitz: "The Teaching of Preventive Medicine in Europe", at 5 p.m. (succeeding lectures on Oct. 18, 19, 20 and 21).

TUESDAY, Oct. 18

Eugenics Society—(at the rooms of the Linnean Society, Burlington House, Piccadilly, W.1).—Dame Helen Gwynne-Vaughan: "The Contribution of Plants to the Study of Heredity", at 5.30 p.m.

Hackney and New College, London—(Drew Lecture at the Memorial Hall, Farringdon Street).—Prof. John Macmurray: "The Conservation of Personality."

Imperial College of Science and Technology.—Air Commodore J. A. Chamier: "Air Power", at 5.30 p.m. (succeding lectures on Oct. 25, Nov. 1, 8, 15 and 22).

University of Leeds.—Prof. John Garstang: "Further Discoveries at Jericho", at 8 p.m.

Royal College of Physicians—(Harveian Oration).—Sir George Newman, at 4 p.m.

WEDNESDAY, Oct. 19

Folk-Lore Society—(at University College, Gower Street, W.C.1).—Mr. Bertram Thomas: "Arab Folk Stories Heard in the Rub' al Khali", at 8 p.m.

THURSDAY, Oct. 20

Bedford College for Women—(Fawcett Lecture).—Dr. C. R. Fay: "Women as Wage-earners and the Significance thereof in the Development of Economic Theory", at 5.15 p.m.

Chadwick Public Lecture—(at the Royal United Services Institution, Whitehall).—Sir Humphry Rolleston, Bart.: "The Pioneers and Progress of Preventive Medicine", at 5.15 p.m.

Child Study Society, London—(Cockburn Memorial Lecture).—Dr. P. B. Ballard: "Thirty Years' Progress in London Education", at 6 p.m.

Institution of Electrical Engineers—(Inaugural Address).—Prof. E. W. Marchant, at 6 p.m.

FRIDAY, Oct. 21

North East Coast Institution of Engineers and Shipbuilders—(Annual General Meeting).—Mr. R. J. Walker (Presidential Address).

CONTENTS

SUPPLEMENT

Practical Policies for the Countryside

INTEREST in the countryside for its own sake is penetrating into the life of the people more rapidly and more extensively than it has for two hundred years. Few would wish to range themselves, nowadays, with that eighteenth century parson of Elsdon in Northumberland who reported that the summer-time moors around him were covered by the purple flower of a plant called ling, which made the landscape "indescribably hideous"; and fewer still, as Prof. G. M. Trevelyan reminded us in his Rickman Godlee lecture, would agree with General Wade's civil adviser when he described the bare tops of the Scottish Highlands as producing "the disagreeable appearance of a scabbed head" and the hill-masses themselves as presenting no more than "stupendous bulk, frightful irregularity, and horrid gloom". The revived use of the highway, facilities for rapid transit, encouragement of walking, the resurrection of the foot bicycle, are at once the expression and in part the cause of this new appreciation of Nature. In the Northern Highlands this summer we have wondered at the full bus-loads of townsmen from Glasgow, Blackpool, London and elsewhere making the grand tour to John o' Groats and back: the choice of such a holiday is significant, the experience must be adding to the multitude of those who treasure memories of Nature's grandeur and beauty.

Clearly, then, there is a vast and increasing body of opinion in Great Britain, and that not confined to one or other of the artificial classes of the people, which is interested in the beauty of the countryside, and would resent interference with the amenities from which pleasure and inspiration are derived. Yet there can be nothing more certain than that in many places amenities are threatened and in others are rapidly disappearing. Industry lifts its smoking chimneys, or disfigures waterfalls, or remodels lakes far from the populous haunts of men. The town spreads into the country; it "must expand and the suburb is a straggling compromise between town and country, ill-planned from the urban point of view and equally disregarding the landscape as such", as the president of the Council for the Preservation of Rural England put it. The townsman spreads himself over the countryside, and thrust by the new facilities for travel into a Garden of Eden where flowers flourish without the toil of cultivation and the stimulus of artificial manures, plucks

to his heart's content, blazing his mark upon the face of Nature as senseless louts scratch their initials upon monuments of antiquity.

Some of these interferences may be necessary, for no one would hold that the well-being of mankind is to wait upon, say, the preservation of the natural margin of a Highland loch; but some are unnecessary in their present aggravated form, and yet they take place in spite of that vast body of public opinion to which we have referred. The reason is that for the most part the public sense of amenity is little more than a hazy goodwill, indefinite, unorganised, without a clear objective, unaware of a means of carrying out what it feels to be desirable. It receives a certain amount of expression through the activities of societies such as the Councils for the Preservation of Rural England and Scotland, the Society for the Promotion of Nature Reserves, the Commons, Open Spaces and Footpaths Preservation Society, the Road Beautifying Association, the Green Cross Society, the Men of the Trees, the Royal Society for the Protection of Birds, and so on; their very number and variety indicate the scattered forces behind them. But even these bodies, representing the enthusiasts, fail to reach and collect the mass of ordinary opinion altogether or almost ready to support their endeavours. What the countryside needs is the organisation of the hazy goodwill which so far, if it reaches the level of expression at all, finds expression only in subdued grumblings and in occasional outbursts in the daily Press.

The need has been foreseen and a way has now been pointed for the concentration of effort on behalf of the amenities, of landscape, of flora and of fauna. A year ago the Committee of the Corresponding Societies of the British Association for the Advancement of Science recommended the Council of the Association to instruct the president of the Conference of Delegates to direct attention to "the assistance local societies can render to the preservation of the amenities of their own areas and especially of the flora and fauna of the countryside". The president was Sir David Prain, and the sympathy and good wishes of the scientific world will be with him in the illness which unfortunately prevented him from delivering his address in person. But the address has been printed and, as becomes the product of Prain's nationality and boreal University, it is a dry, direct, practical document, a guide to practical policies in the countryside which ought to focus vague hopes and therefore ought to be the constant companion of those country lovers who believe in getting things done.

There is a fundamental divergence of interest between the dweller in towns and the countryman, and to this Sir David Prain traces the inroads upon wild Nature which have been so marked in our land since the industrial revolution. Directly, it has destroyed "the amenities and the flora and fauna of the countryside by creating clouds of smoke that obscure the sun, discharging acrid fumes that vitiate the air, emitting fetid waste that pollutes our streams, and heaping mine tailings on what was once fertile soil". It was the scientific worker, by the way, who brought partial relief from these evils by convincing captains of industry that costs could be reduced if smoke were consumed, and profits could be increased by the utilisation of waste products.

Indirectly, the influence of industry crept still further into the heart of the country. Industry drew a proportion of the rural population to the towns, and having chained it there demanded that the depleted countryside should furnish more and more food to meet the needs of town workers, who no longer raised food for themselves. For a time town and country became linked in a common interest; agriculture, knowing that it had the solid support of the towns, cultivated the wastes, often at great capital outlay, it intensified its methods of husbandry, planted shelter belts of trees and larger woodlands; and the town on its side encouraged the building of highways along which agricultural produce reached the towns and manufactured goods the country. But the fundamental antagonism was hidden and not eradicated, for "the moment English industry found it possible to obtain supplies of food from other sources, English urban sympathy with English rural interests vanished like a morning mist". That may be true of the commercial side of urban life, but it surely fails to give due weight to the great body of townsmen who appreciate the open country, sometimes with fresher vision and deeper feeling than the countryman himself, and whose support is the mainstay of the associations created for the preservation of its amenities.

Whatever may be the relationship between town and country, it is certain that at the moment the latter requires all the forces it can muster on its behalf. Sir David Prain points to the local societies as the proper bodies for the effective organisation of goodwill towards the countryside and its wild inhabitants. They must sound, and

if need be create, local feeling to meet the threats of unnecessary encroachment. They must work hand in glove with the local authorities, supporting and forwarding their schemes if they are good, offering better suggestions, in place of sterile opposition, if they are unsatisfactory. They must make themselves familiar with the technique of saving and preserving landscape, flora and fauna; and to this technique a great part, the most practically useful part, of the address is devoted.

We take it that the address will be used as a handy guide to the preservation of Nature in Great Britain, so that there is no need to discuss its recommendations in detail; but a few samples of Sir David Prain's advice will show how directly he is driving at the mark. If the threat be to the general amenities of the area or to some special view-point or beauty spot, a local society can scarcely fail to benefit by the experienced advice of the Council for the Preservation of Rural England or of the executive committee of the National Trust for Places of Historic Interest or Natural Beauty. Experience shows that the only safe course in most cases is to purchase outright and render inalienable the threatened spot. But a local society should hesitate to burden itself with the possession and care of such a property; it may raise funds for purchase, create an endowment for future maintenance, but as a rule its final step must be to request a permanent, legally constituted body such as the National Trust to accept the property. This course premises that before any steps have been taken the local society will have consulted the Council of the National Trust as to the suitability and desirability of preserving the particular place of interest and that, therefore, it will have the moral support of that body in its appeal for funds.

A difficulty arises, however, if the objects to be preserved are not places of beauty or general amenity, but particular representatives of the flora or fauna; for "absolute protection of wild life in properties acquired to safeguard amenities is not easily provided: properties acquired to safeguard amenities must remain accessible to the public they benefit". Sir David Prain is of opinion, and many agree with him, that the rarities of fauna and flora can be retained for posterity only by the exclusion of the people. This calls for the creation of a special Nature reserve or sanctuary, and so for a different method of treatment. "A sanctuary need not be 'a place of natural beauty'; even if it be, in fact, entitled to be so regarded, the National Trust may be debarred from accepting the burden of ownership, because a sanctuary becomes valueless unless access to it is denied." In such case the local society interested would approach for advice and support the Society for the Promotion of Nature Reserves, a body empowered by charter to own sanctuaries of the kind, which, largely in view of the attitude of 'collectors', require much more strict patrolling, and therefore a larger endowment for upkeep, than simple beauty spots.

Sometimes local societies will find that "the agencies inimical to wild life in their own areas have become so powerful that the establishment of a 'sanctuary' is impracticable, and that the only means of conserving the wild life once characteristic of the neighbourhood is to acquire a suitable site and convert this into an 'asylum', for such plants, insects and birds, known to have been at one time native there, as can be placed in or attracted to the 'asylum'." Such an asylum must be as freely open to the public as "a place of natural beauty", but the difficulties arise that while its accessibility to the public should prevent the Society for the Promotion of Nature Reserves from accepting ownership, its artificial origin should preclude the National Trust from doing so. Here again the local society will find its course indicated; upon it must fall the burden of raising funds for establishment and maintenance, but this done there should be no difficulty in obtaining the consent of the local authorities to accept the responsibility of ownership.

These are high ideals, difficult of attainment, which are held up for the consideration of the local societies; but the very fact of their formulation may suggest a definite direction for activities hitherto dispersed in less important ways. The path will not be easy: "Local societies may anticipate many difficulties and much opposition, some of it due to self-interested motives, but more of it due to misunderstanding. That need not discourage them, provided they are on good terms with and enjoy the sympathy of their own local authorities. With that behind them, local societies can do much." Every likely problem Sir David Prain has passed under review and accounted for, and it will be a fitting crown to his labours in this field that in the years to come places of natural beauty will be preserved, and Nature reserves and asylums for the conservation of local wild life will spring into being through the organised efforts of local societies following his wise guidance. J.R.

Geographical Study of Society and World Problems*

By Prof. H. J. FLEURE

IT has been assumed in many discussions that mass-production and commerce on a large scale represent a new mode of life, a form of society, that is conquering the world and must disintegrate older modes of social life and organisation. However true this is, there are limitations, obvious now that production far beyond immediate selling possibilities is causing so much difficulty. It is truer to say that various types of society are trying to graft on to their ancient heritage this new scheme of mass-production.

It may have been useful, up to a point, to think out the increase of production through specialisation as Adam Smith does in his famous argument about pins, but there was need for far more thought than seems to have been given to the maintenance and development of social life in the various environments Nature provides and man adjusts. Social forms result from interaction between men and their environments, and the lessons learned and the ideas selected and developed in different cases have been very different. This is a legitimate and important sphere of work for the student of geography. In each case, the people and their form of society are so much a part of the other that, whatever changes mass-production may bring, they want to, they must in fact, keep a large measure of continuity from their past.

They have nearly all once been, in the main, self-contained groups, or, at least, external commerce has been subordinate to internal exchange. The idea of the self-contained unit is thus very deep-rooted. With great effort the village has come to feel itself part of the nation, which has clamoured for opportunities of self-expression. Many a nation naturally, therefore, seeks to be self-contained, all the more if it feels that specialisation and consequent dependence on imports is going to give it an inferior position.

HUNTING GROUPS

We may distinguish at least three main phases of expansion of hunting cultures, possibly all associated with *Homo sapiens*, from an Arabian-African zone, while another culture has its origins and associations still doubtful. The interest of these ancient cultures here is that the two or three later stages among them occur mingled in South Africa, apparently also in India, and among the Australian natives. In fact, if we use as a hypothesis the idea of drifts from northern Africa and south-western Asia, we have a key to some modern distributions of hunting peoples. These societies are either in what are ultimate corners or in areas of special difficulty; elsewhere they have been superseded by agriculturists. The pygmies of the equatorial forest of Africa are remnants in a region of hot, wet climate where debilitation makes achievement difficult. The Bushmen of south-western Africa are in a region of sheer poverty in a far corner. The Veddah and some jungle tribes of southern India are in another far corner under conditions that forest or jungle makes difficult. The Australians and recently extinct Tasmanians are in a far corner, isolated by orographical changes. The pygmies and some other hunting groups of Malaya and the East Indies and Philippines are, again, in what are almost ultimate corners, isolated by land-sinking, and also in regions of warm, wet forest.

AGRICULTURAL PEOPLES

The post-glacial intensification of the desert in northern Africa and south-western Asia caused pressure of population on the Nile and Euphrates and possibly the Indus as well, all rivers with regular floods running through dry or then fairly dry open country with a warm season. In or near these river valleys there arose the art of cultivation. All these rivers permitted and encouraged irrigation, and the deposit of silt from floods gives a renewal of fertility, so exhaustion of the soil was not a problem of early cultivators near the rivers. The courses of the Euphrates and Indus were conspicuously subject to variation, whereas the Nile is confined in its famous slot and its peasantry has gone on from time immemorial until near our own day with a remarkable measure of constancy as regards the economic basis of life.

Domestication of animals was an achievement of very early times too, and, in such regions as the Fertile Crescent with its grass zones, it undoubtedly assumed great importance and led to the beginning of age-long conflicts and interactions between herdsmen and cultivators. The herdsmen, basically a close corporation gathering around the flocks and needing men to add to their strength for defence, as well as discipline and organisation to maintain unity, have often dominated peasant neighbours; but this special ability appears to have been much developed when the horse was acquired as a companion and helper.

The bearings of the introduction of cultivation on social life and organisation have obviously been of the first importance. There was an observable sequence that made argument more solid than it was likely to be in the days of hunting when accidental coincidences loomed larger. The habit of prevision extended itself through calculations of the coming of the floods and correlated study of the heavenly bodies to the framing of a calendar. There was a further extension of prevision beyond that to a succession of years—namely, to a succession of generations specially associated with the domestication of animals and with the family.

Thought, drawn out towards the future, seems just as naturally to have run back into the past,

* From the presidential address to Section E (Geography) of the British Association, delivered at York on Sept. 1.

giving rise to genealogies which are one of the germs of history and also to rites of reverence paid to ancestors. These rites, not unnaturally, are specially marked in regions such as China which owe so much of their civilisation to early interactions of herdsmen and cultivators on the ways from central Asia. It is of interest to note that the large household, linked by real or sometimes assumed blood relationship, seems a social feature of basic character among the cultivators of northern China, and in other forms is notable among other cultivators around the edges of the great steppe, the famous Zadruga of parts of the Balkan peninsula being a case in point in a region in which interactions between herdsmen and cultivators have been and still remain most important features of life. The Russian Mir sometimes had a like origin. It is naturally a social development in large measure antagonistic to the growth of nationalism.

Along with the primarily psychical development accompanying the rise of cultivation went the linking of society with a definite piece of land through the establishment of the settled life. This association is one of the most important features of settled society, and leads to the idea that the living hold a trust from their forefathers and will pass it on to future generations.

Whatever may be found hereafter concerning the phases through which the early cultivating societies developed in their primary homes, there is little doubt that the spread of their scheme of life occurred in most directions in two stages. The first went with the hoe, used chiefly by women, and with domestic animals for food or milk, but not for work, and the second with the plough drawn by domestic animals under male control.

The first of these two rather artificially contrasted stages is the one that spread into intertropical Africa. There were special difficulties here. First the climate made steady prolonged efficient exertion difficult in many areas. Then the fundamental crops, wheat and barley, would not thrive in most parts, and inferior grains and other plants became the important crops. Further, there were practically no wild plants in intertropical Africa that the native cultivator contrived to domesticate; so progress depended largely on plants deliberately introduced, as for example via Egypt or by Arabs, Portuguese, etc., in later times. The introduction of maize, manioc, etc., from America has made a huge difference to Africa. Fly belts in several regions, also lack of salt and phosphorus deficiency, and no doubt climatic factors, limited the value of domestic animals in intertropical Africa.

Archæologists think agriculture spread into central Europe at first with the hoe and the non-permanent village that is a feature of parts of intertropical Africa; and there are indications of the same scheme in forested and therefore backward parts of central India and elsewhere in south-east Asia as well as in north Korea.

Agriculture with the plough has now ousted this scheme from Europe and most of Asia and, in this superior stage, the village becomes more permanent: either a rotation in the use of lands is established and the households have their strips in each of the village lands, or a portion of the village land specially enriched by manure from stock folded on it may be cultivated nearly every year, and some portion of an 'outfield' may be used as may be required or may be possible.

In the regions with irrigation or plough agriculture or both, the differentiation of crafts went much further than among societies with hoe cultivation. Exchange developed more considerably and there are towns or cities, fundamentally centres of exchange and of handicraft, and often of a priesthood and government. Cities are not found in inter-tropical Africa save in a few spots where they are due to intrusive influences of fairly recent date.

The nomadic or semi-nomadic societies of inter-tropical Africa live on their cattle, and by hunting and collecting, as well as by raiding those which are more sedentary and less ready for war. The nomadic and semi-nomadic societies of Europe, Asia and northern Africa have in many cases the important auxiliary activity of trade, and use their beasts as carriers. Moreover, they have typically developed or contributed to the development of stations, which have in many cases become centres of trade and religion, that is, sacred cities, near the bounds of the waste or in oases. In China, India and the Fertile Crescent the semi-nomad, especially after he acquired the use of the horse, found it possible to dominate the cultivator, and seems often to have contributed an elaboration of organisation to the group of social units; villages and their focal towns become grouped into larger entities.

Consciousness of Kind

In west, north-west and parts of central Europe, early development was slow because the food plants and animal breeds had to be acclimatised, and the problem of soil exhaustion was serious even if mitigated where the subsoil was of loess or related material. Nevertheless, there can be no doubt that settled populations in central and western Europe practising agriculture and living in villages were much more numerous in far pre-Roman times than it was customary to think a generation ago.

The spread of Islam in the Mediterranean region cut old trade routes for a time, and this increased the poverty following the decline of the Roman Empire, so that towns and cities went through a bad time, but apparently in several areas there was a marked increase of rural settlement.

As a hierarchy of social units re-established itself, growing mainly from local roots instead of from an external influence such as that of Rome, it is natural that such hierarchies should spring up where there was mutual comprehension of language in groups of villages and their focal market towns,

and cathedral cities in France. Moreover, charters and grants and agreements written in the vernacular came to be increasingly important, while the use of the vernacular in courts of first instance developed folk-speech. It is apparently a combination of all these factors that has maintained the distribution of the peasant languages of Europe without any change of great importance since the Middle Ages.

The idea of the city can be traced eastwards and northwards from France and the Rhine in the early Middle Ages, and, in relation with this, often, at the present day, the life of a town connects it with regions farther west, while the peasant life round about knows nothing of this. The Renaissance, being essentially an urban movement, accentuated this, and we note the French leanings of part of the upper classes in Alsace contrasted with the Alemannic tradition of the peasantry, German aristocracy and Danish common folk in parts of Slesvig, German (including Yiddish) affiliations of towns in Poland as against Slavonic life among the peasantry, Polish affiliation of towns and the upper classes in East Poland as contrasted with Lithuanian (in the north) and Ruthenian (in Eastern Galicia) traditions of the peasantry.

Traditionalism and Individualism

The problem was greatly deepened by another sequence of development. The Renaissance, whatever else it may have done, was a potent factor of the rise and spread of individuality. After it, much larger numbers of men in Europe became less members of a traditionalist community and more definitely persons with ideas of their own to express.

In some parts, notably in France, these changes, and even great political convulsions, long left some basic facts of society untouched. The peasantry long remained attached to, almost worshippers of, their soil, even if in parts of the west and south of that country this is no longer the case. The peasant acquired more dignity, but the village remained an entity; men still often make it their main ambition to hand on an improved farm to their descendants. The town too is often still essentially the focus and market for its region, and it often still carries on a number of small industries for the benefit of its neighbourhood. Its bourgeois are peasants only slightly modified. The idea of maintenance, rather than that of expansion on an English, German or American scale, is strong in many minds and France, characteristically, makes external trade subordinate to internal production for use and exchange. The reasonable assurance of her wheat, root crop, potato, and, but for a few calamitous years, vine and apple harvests, thanks to sunshine, has contributed a great deal to this, and has helped the French people to modify into modern forms the age-old feeling of a trusteeship (of the sacred soil) handed along the generations.

Britain's harvests have long been less secure because of summer rains and coolness, and, in the eighteenth and early nineteenth centuries, there grew first a widespread maritime commerce, and then manufacturing industries—in fact, the Industrial Revolution.

The home population came to exceed by a great deal the numbers that could be kept busy supplying the needs of their fellow citizens. Britain's export trade came to be her mainstay. The contrast between French and British development was thus extreme and startling.

Industrialism spread from Britain to Germany and led to a parallel increase of population. The German effort also had its aim moulded politically by the desire to rise out of an old position of political inferiority and disunion. Further, the historic cities of Germany in several cases, such as Nürnberg, Frankfurt-am-Main, Köln, Leipzig, and so on, had their situations predetermined by major physical considerations, and must be important centres so long as Germany is a land of organised civilisation. This fact and the related one of the finding of coal near the zone of gradation from the hills to the northern plain, that is, a zone of cities, led to the development of modern industry in several cases in historic towns, whereas in England the greatest developments took place in what had previously been small places. Both national and municipal authorities in Germany, therefore, had a larger and more direct share in the directing of industrial growth than was the case in Britain.

If we think along these lines we see why, quite apart from wars and questions of external political ambition on one side or the other, it has come about that the French people have been gravely anxious. Here are two enormously increased units, Great Britain and Germany, both dependent on export trade, neither able to live with any reasonable standard for the great multitude mainly on the produce of its soil.

The spread of large-scale industrialism makes the problems still more serious. There are now several States that have populations exceeding what their soils can support unless science intervenes afresh; all therefore compete for an increasingly precarious export trade, all are in danger of finding groups of their people, with highly specialised machine-tending activities and corresponding inelasticity of mind, suddenly thrown out of employment and unable to adjust themselves to new lines of enterprise.

Meanwhile, nearly half mankind, in the monsoon lands of Asia apart from Japan, is being shaken out of its traditionalist schemes by contact with the west, and nationalist ideas are germinating in various ways alongside schemes of industrial development that borrow from the west to such an extent as to be a danger to indigenous society. Then the newer lands which have received the later overflow of modern Europe, and seemed likely to become producers of raw material for Europe, are also being forced along the same line of nationalist development. They have borrowed

freely from Europe (chiefly Great Britain and France) and more lately from America, and have consequently found themselves faced with the duty of finding large amounts of interest. This interest often is not by any means earned by the working of the schemes on which the money was spent. To meet this call for interest, exports must largely exceed imports, and so tariffs are introduced to keep down imports, and local industries are started.

On all sides, in the first great burst of mass-production, local boundaries seemed to have been swept away. It is probable that our social thoughts and plans will have to regain contact with mother earth, each group basing itself on its own soil, but evidently not in the old sense of a self-contained isolation. Interdependence of all on each is a new feature that will become increasingly important, and one of the geographer's tasks is to try to see both the roots of each society in its own soil, and its relations to others.

White Dwarf Stars*

IN this year's Halley Lecture, Prof. E. A. Milne presents us with a systematic account of white dwarf stars in theory and observation. There is no doubt that, in view of their peculiar physical properties and the excellent example they provide for a successful application of modern quantum mechanics, white dwarfs are among the most interesting of natural objects. But this interest arises, of course, not so much from the direct observations as from the derived density of the star and its theoretical interpretation. It is therefore very valuable, at least to the non-astrophysical scientific worker, to have the facts and theories about white dwarf stars reviewed in this systematic way.

Owing to the importance of the existence of matter of great density to general physical theory, it is important to appreciate how direct is the evidence and how independent of any detailed theory. The well-established white dwarfs like Sirius B have a mass directly deduced from the law of gravitation and an observed double star orbit. They have an absolute luminosity determined from their distance (parallax) and their observed apparent luminosity. In view of the simplicity and universality of the theories involved in these deductions, no one will dispute that mass and absolute luminosity have the certainty of direct observations. To determine a density, a radius is required as well as a mass, and the radius must be deduced from the absolute luminosity and the surface temperature via the thermodynamic laws of radiation and the theory of the flux of radiation emerging from a gaseous atmosphere. Even in this step the maximal observational and theoretical uncertainties are not very great. If we know the surface temperature and the absolute luminosity, we can determine the surface area of the star, apart from possible uncertainties, at most of the order of 50 per cent, arising from conceivable errors in the radiative theory. All depends, therefore, on a determination of surface temperature, to which parameter the resulting mean density is rather sensitive, as it varies as the sixth power of this temperature.

There are two main methods of determining surface temperature. One can assume that the quality of stellar radiation, apart from line absorptions, follows closely Planck's black body curve; after observing the energy distribution in the spectrum of the star, one can fit Planck curves to it and thereby determine the temperature from the curves of best fit. This method is known to underestimate the temperature considerably, especially for the higher surface temperatures, and is not reliable for the stars in question. But the theory of ionisation in stellar atmospheres and of the production of absorption lines in an ionised atmosphere enables one to assign a surface temperature when the surface value of gravity is known and also the spectral *type*. The possible resultant uncertainties in this application of theory do not appear to be very great. It is true that the surface value of gravity is not known initially, but it is known when the radius is determined, and the problem of determining the surface temperature is therefore solvable in theory, and also in practice, at worst by a process of successive approximation. This is admittedly the most uncertain step in the deduction of the radius and therefore of the density, but if we suppose that a maximum uncertainty of a factor of 10 could thereby be introduced into the density, we shall have allowed more than amply for all errors at present conceivable, and the existence of excessively dense matter must be regarded as fully established. Taking a reasonable view of probable observational and theoretical uncertainties, it is most unlikely that the current accepted mean densities for the best determined white dwarfs, such as Sirius B, are in error by a factor nearly so large.

Prof. Milne then passes on to the problem of the frequency of such dense matter in our galaxy. There are very few directly well observed white dwarfs, but the conditions for a good determination, owing to absolute faintness and the necessity for a well determined parallax and double star orbit, are very severe, and the fact that we know only four such stars is consistent with a great abundance of such stars in our galaxy. The essential conditions for a white dwarf are a relatively low absolute luminosity combined with a high surface temperature. There is reason to believe that these properties are found together in two remarkable classes of stars, the central stars of planetary nebulæ and ex-novæ. The evidence is reviewed by Milne, who concludes provisionally that the case is proved.

If correct, this conclusion is of the utmost importance, not so much for the greatly increased abundance of known dense objects as for its possible

* "The White Dwarf Stars", being the Halley Lecture delivered on May 19, 1932, by Prof. E. A. Milne. (Oxford: Clarendon Press. 1932.)

evolutionary significance. It has been suggested by Prof. Milne, on purely theoretical grounds, that stars in general are in one of two states which may be called expanded and collapsed (Milne's centrally condensed and collapsed configurations respectively), and that the passage from one state to the other sets in at a certain critical stage in the evolutionary history and is of a cataclysmic nature. It is suggested, in short, that the evolving star, perhaps towards the end of its radiating life, becomes a nova and then a white dwarf. The outburst of radiation during the transient nova stage is the star's means of getting rid of the great difference of energy between the contiguous expanded and collapsed states. While it is still too early to be confident of the correctness of the theory underlying Milne's suggestion, the suggestion itself is a very happy one, likely—right or wrong—to prove extremely fertile. Milne's discussion already shows that an evolutionary sequence, ordinary star—nova—white dwarf, is by no means irreconcilable with the known facts, and indeed co-ordinates a great part of the facts in a most satisfying manner.

The second half of the Halley Lecture describes the present state of knowledge of the theory of stellar configurations—the generalisations that have sprung in the last three years from Eddington's pioneer work on the radiative equilibrium of a sphere of perfect highly ionised gas. These generalisations are still in an early stage of development. Milne himself, who initiated them and has been the prime mover in their development, would, I believe, be the last to claim that the equilibrium states of any model yet computed really reproduce the properties of any ordinary star. The collapsed white dwarf states appear to be simpler and to be satisfactorily accounted for by models already computed. They consist mainly of a rather cool, dense, almost isothermal core, the properties of which are controlled by those of a degenerate electron gas. But although existing models have not yet been made to mimic the observed properties of ordinary stars, we can see that this study of models has already infused new life into the theories of stellar evolution, and has taken us perhaps one long step nearer to the goal so rashly proposed as attainable in the last sentence of Eddington's "Internal Constitution of the Stars"—the goal of understanding so simple a thing as a star.

R. H. F.

The British Association Standards of Electrical Resistance, 1862-1932

FEW realise how much the electrical industry owes to the Electrical Standards Committee of the British Association, first appointed at the Manchester meeting in 1861. We welcome, therefore, the paper entitled "Material Standard of Resistance: the B.A. Coils, 1881–1932", read by Sir Richard Glazebrook and Dr. Hartshorn to Section A (Mathematical and Physical Sciences), at the York meeting on September 1. The Electrical Standards Committee in its first report (Cambridge, 1862) stated that it had first to determine the most convenient unit of resistance and, secondly, the best form and material for the standard representing that unit. The C.G.S. system of measurement was the outcome of its deliberations, and this decision has done more than perhaps any other single act in simplifying and unifying electrical measurements throughout the world.

Experiments were made at King's College, London, by Maxwell and Fleeming Jenkin to obtain the ohm in a material form, and reports giving their results were issued in 1863 and 1864. In Appendix A of the Report for 1865 it was recommended that the material of the wire from which the resistance standard be made should be an alloy containing 66 per cent silver and 33 per cent platinum. It was agreed that copies of the standard should be made and preserved at Kew Observatory. In the Report for 1867 a table is given of the values of the standards in question. This Committee was dissolved in 1870. Soon after Maxwell's appointment as Cavendish professor of experimental physics at Cambridge, the coils were brought to the Cavendish Laboratory and were used by Chrystal in 1876. Lord Rayleigh succeeded Maxwell in 1879 and at once became interested in electrical measurements. Rowland of Baltimore had thrown doubts on the accuracy of the absolute measurements of the B.A. Committee. Rayleigh and Schuster's experiments at Cambridge confirmed these doubts, and from 1881 onwards great activity was shown at the Cavendish Laboratory in investigating the question of electric units. In 1879–81, Dr. J. A. Fleming made a very careful comparison of the B.A. coils. He found that their relative values had changed appreciably, and he adopted as a definition of the B.A. unit the mean value of the resistance found from all the coils at the temperatures at which they were originally said to be correct.

The Electrical Standards Committee was reappointed in 1880; and in 1881, R. T. Glazebrook became connected with the work. He was appointed secretary in 1883, and the coils were in his charge from that date until 1919. They are still at the National Physical Laboratory. The Standards Committee was dissolved in 1912. Up to that date, comparisons of the coils between themselves were continually in progress, and their values were determined in ohms and also in terms of the length of a column of mercury by Rayleigh, Glazebrook, Fitzpatrick, and F. E. Smith. The records show that most of the coils have changed appreciably during their long life, but that the two platinum coils included in the original group have remained unchanged.

The point of most importance that emerged from Sir Frank Smith's measurements of 1908 was the performance of the two platinum coils, now marked 'D' and 'E'. The value of these coils in B.A. units in 1888, 1908, and 1932 obtained from a comparison

with mercury tubes, assuming that the resistance of 1 metre of mercury is 0·95352 B.A. units, is given in the accompanying table:

Coil.	1888 (R. T. G.).	1908 (F. E. S.).	1932 (Hartshorn).
D	1·00013	1·00012	1·00011
E	1·00073	1·00072	1·00071

The coils have been very carefully intercompared this year at the National Physical Laboratory and their value determined in terms of the international ohm by Dr. Hartshorn. The international ohm is defined as the resistance at 0° C. of a column of mercury 106·300 cm. in length and 1 sq. mm. in cross section. Tables are given illustrating how the values found for the coils during the last sixty-five years have varied. These show that considerable variations appeared prior to 1888. These depend probably on errors arising in the temperature determinations of 'D' and 'E', as an uncertainty in the temperature of these coils of 0·1° C. implies an uncertainty of 0·0003 B.A. units in the resistance measurements.

In the platinum-silver coils 'F' and 'G' appreciable changes were noted between 1880 and 1908. These are probably due to the fact that during that period the coils were on several occasions measured at 0° C.; strains may have been produced at the soft soldered joints. In recent years, when the coils have been maintained at a temperature not far removed from 16° C., the changes have been remarkably small.

The main conclusion to be drawn from the series of investigations from 1865 to the present date is that the platinum coils 'D' and 'E' have retained their value unchanged, while changes have occurred in all the coils made of alloys. These changes are partly due to the violent temperature changes to which all the coils have been subjected at various times.

We may also conclude that pure metals like platinum are usually more stable in their properties than alloys like manganin. Unfortunately, the pure metals suitable for standards have temperature coefficients varying from 0·003 to 0·007, so measurements would have to be taken at 0° C., as this is practically the only temperature at which they can be maintained sufficiently constant.

Obituary

Prof. W. Stirling

William Stirling, formerly Brackenbury professor of physiology at the University of Manchester, died on October 1. Prior to his going to Manchester he held the regius chair of the Institutes of Medicine at Aberdeen.

Stirling was born at Grangemouth in 1851, received his early education at the Dollar Academy and then became an undergraduate at Edinburgh. Here he had a career of great distinction, graduating as B.Sc. in 1870 and two years later as D.Sc., M.B. and C.M. In his medical final examination he was awarded first class honours. He also gained the Baxter scholarship, the Falconer fellowship and Ettles prize. His thesis in 1875 on "The Summation of Electrical Stimuli applied to the Skin" brought him the M.D. degree and with it the gold medal. After his student career in Edinburgh he worked in Leipzig, Berlin and Paris, and then returned to Edinburgh as demonstrator under Rutherford. His election to the regius chair at Aberdeen shortly after this time and when he was but twenty-six years old, indicates clearly the great promise of his early years and the esteem in which he was held.

After eleven years in Aberdeen, during which time he introduced there the practical teaching of physiology, Stirling was elected as successor to Arthur Gamgee in the chair of physiology at Owens College, Manchester. Here he remained until his retirement in 1919.

Stirling became a professional physiologist at a time when the teaching of physiology in many of the medical schools of Great Britain was inadequate and very little research work was done. In France and Germany, however, the subject in the hands of such masters as Bernard, Helmholz and Ludwig, had developed into an important experimental science. It is not surprising, therefore, that Stirling's sojourn abroad inspired in him a great affection for the men under whom he had studied, and this was apparent from his frequent references to them in his lectures and in private conversation. Carl Ludwig especially was held by him in great regard.

Nevertheless, although in his early post-graduate days Stirling carried out promising research work, he eventually became an interpreter of the work of others rather than an investigator himself. Both at Aberdeen and in Manchester, he introduced elaborate methods of teaching and was largely responsible in the latter school for the extension of the medical building which houses the present physiological laboratories. In addition to his work for his own department at Manchester, Stirling acted as Dean of the Medical School from 1902 until 1913, showing himself to be a capable administrator and devoting himself wholeheartedly to the general welfare of the School. It is probable that these heavy administrative duties coupled with the labours involved in bringing into being the new medical buildings were largely responsible for the attention he devoted to exposition rather than to physiological research. Of his publications, probably the best known are his "Apostles of Physiology", "Outlines of Practical Physiology" and the "Text Book of Physiology" by Landois and Stirling; the last-named being a translation of Landois's book, to which Stirling made many valuable additions.

Stirling was a man who made many friends and did not easily lose them. His fine stature, impres-

sive manner and mode of dress made him a striking figure. Men who were his students still talk of his attractive personality, the great clarity and interest of his lectures and the minute detail with which his practical classes were organised. As a popular lecturer he was in great demand and through this became widely known. This stimulation of interest in biological science in the latter part of last century was probably of great value in gaining support for the scientific departments of the university colleges of the north of England in their earlier days.

In 1904 Stirling received the honorary degree of LL.D. from the University of Glasgow and in 1906 he was Fullerian professor of physiology at the Royal Institution, London. H. S. R.

Dr. F. H. Hatch

THE death of Dr. Frederick Henry Hatch on September 22, at sixty-eight years of age, will be regretted by numerous friends in mining and metallurgical circles. Dr. Hatch was born in London, and after studying at University College, proceeded to the University of Bonn, where he took the degree of Ph.D. He spent six years as a member of H.M. Geological Survey, when his work was largely petrological, dealing especially with the igneous rocks of Scotland.

Dr. Hatch recognised, however, that there was a great opportunity for a geologist in the then newly discovered goldfield of the Witwatersrand, and in 1892 he resigned his appointment and went to the Transvaal, where he soon achieved a high reputation as a mining engineer and consulting geologist. He undertook exploration work of the highest importance for various gold-mining interests, his most significant work in Africa being that in connexion with the development of the eastern extension of the Rand goldfield, in the region where the reefs disappear below a great thickness of newer rocks.

In 1895 Dr. Hatch became associated with Cecil Rhodes and John Hayes Hammond in the development of Rhodesia, but the Jameson Raid and the Boer War caused such a general disturbance of this and all his other work that he left Africa for some time, visiting the United States, Canada, British Columbia, and Abyssinia. He also spent a year in India, investigating the gold resources of that country for the Government. His report on the Kolar goldfield may be regarded as a classic in mining literature. At the close of the Boer War he returned to Johannesburg. An intensive boring campaign under his advice finally revealed the structure of the East Rand, which is now the most important producing area, and rendered its development practicable. About 1906 Dr. Hatch left Africa for England, where he established a large practice as a consulting mining engineer, visiting Siberia and other countries. In 1909 he undertook on behalf of the Government an investigation of the mineral resources of Natal.

From 1910 to 1913 Dr. Hatch resided in Cambridge, where he lectured on economic geology and presented to the University a very fine collection of specimens of metalliferous ores collected during the course of his professional work. In 1914 he was president of the Institution of Mining and Metallurgy.

After the outbreak of the War, during which he lost his two elder sons, Dr. Hatch was engaged in the Ministry of Munitions and played a prominent part in the organisation of home supplies of iron ores, a piece of work which was of immense service in the organisation of victory. After the War he reported on the condition of the iron and steel works in Lorraine, in the occupied areas of Germany, in Belgium and in France, and then became director of the Mineral Resources Development Branch of the Board of Trade and technical adviser to the Mines Department.

In addition to all this, however, Dr. Hatch was a man of high attainments on the side of pure science. He was the author of books on mineralogy, petrology, and ore deposits which did much to render these subjects intelligible to the average student. The number of editions is evidence of their success and usefulness. In the last few years petrology has become infinitely and perhaps unnecessarily complicated, but nevertheless many of the existing classifications of rocks bear a strong imprint of the common-sense system of the editions of Hatch's "Petrology" of 1907 and later years. R. H. R.

Sir Everard im Thurn, K.C.M.G., K.B.E.

THE death of Sir Everard Ferdinand im Thurn, colonial administrator, anthropologist and naturalist, at eighty years of age, took place on October 8 at his residence, Cockenzie House, Prestonpans. The son of John Conrad im Thurn, merchant-banker, he was educated at Marlborough and at Exeter College, Oxford. Before going to Oxford he had already in 1869 published a book on the birds of Marlborough. In 1877 he went to British Guiana as curator of the museum. He there took up the scientific study of the country and its peoples, being the first to ascend Roraima, and publishing a work on the botanical results of that expedition. In 1882 he was appointed judge in the Pomerun District and in 1890 was made Government Agent in the North-Western District. He joined the staff of the Colonial Office in 1899, having been made C.M.G. in 1892, and was made C.B. in 1900. He was appointed Colonial Secretary and Lieutenant-Governor of Ceylon in 1901 and Governor of Fiji and High Commissioner of the Pacific in 1904. In the following year he was promoted to K.C.M.G. and in 1910 he retired. In 1918 he was made a K.B.E. From 1919 until 1921 he was president of the Royal Anthropological Institute, and on taking up his residence in Scotland shortly after he had held that office, he helped to organise and became the first local president of the Edinburgh branch of the Institute.

Sir Everard im Thurn was the author of many papers on the history and geography of British Guiana, Ceylon and the South Seas. He also wrote a number of books. "A Tramp with Red-Skins" appeared in 1886 and "A Sketch of the Ceylon Pearl Fishery" in 1903. It was, however, by his "Among the Indians of Guiana" (1883) that his work was best known throughout his life. This, especially in view of the date at which it was written, is an outstanding piece of work, showing a remarkable range in knowledge and understanding of the ways of thought of a people of backward culture—qualities which served im Thurn well as an administrator in the Pacific. The book was for long, and still continues in some degree to be, a standard work of reference for anthropologists in comparative work. His last considerable undertaking was the editing, in conjunction with Mr. L. C. Wharton, for the Hakluyt Society, of "The Journal of William Lockerby, Sandalwood Trader in the Fijian Islands, 1808–9", published in 1925, to which he contributed an introduction and notes embodying a mass of valuable information. Sir Everard himself considered that this book contained his best work.

After his retirement, Sir Everard's leisure was far from unoccupied, and his advice, assistance and knowledge were freely at the disposal of all who were interested in geographical and anthropological questions relating to the South Seas. In 1925 his services to science were recognised by his old college when he was elected an honorary fellow.

WE regret to announce the following deaths:

Mr. A. Chaston Chapman, F.R.S., a past president of the Society of Public Analysts, the Royal Microscopical Society and the Institute of Chemistry, on October 17, aged sixty-two years.

Prof. O. D. Kellogg, professor of mathematics at Harvard University, known chiefly for his work in the calculus, on August 27, aged fifty-four years.

Prof. Edgar James Swift, professor of psychology at Washington University, St. Louis, who has carried out many investigations in applied psychology, on August 30, aged seventy-two years.

Mr. Arthur Silva White, formerly secretary of the Royal Scottish Geographical Society and assistant secretary to the British Association in 1904–9, author of books on Egypt and Africa, on October 12, aged seventy-three years.

Prof. Max Wolf, professor of astronomy in the University of Heidelberg, associate of the Royal Astronomical Society and foreign associate of the U.S. National Academy of Sciences, on October 3, aged sixty-nine years.

News and Views

A Self-Styled Faculty of Sciences

SEVERAL correspondents have sent us copies of a letter and circular which they have recently received inviting them to become fellows of a body having the title "The International Faculty of Sciences", with an office at 36 Gordon Square, London, W.C.1. The preliminary prospectus, issued more than a year ago, did not include the word "International" and was the subject of some severe comments in *Truth* of September 16, 1931. The new circular, which appears to have been widely distributed, invites application to be made for admission "as a Fellow of the Faculty of Sciences" and states that "The application of every candidate for fellowship must be accompanied by a remittance of one guinea." After election, "every Fellow is entitled to use after his name the initials 'F.F.Sc.' ". There is, of course, no relation whatever between this International Faculty of Sciences and the Faculty of Science of the University of London, though the similar title adopted by the new body must lead to misunderstanding in the minds of many people. The president and vice-presidents of this body are stated upon the circular to be as follows:—"President: Prof. H. W. Blood Ryan, M.A., D.Sc., LL.D., Ph.D. Vice-Presidents: Prof. Ingo W. D. Hackh; Prof. R. F. Hunter, D.Sc., Ph.D., D.I.C., A.R.C.Sc.; Prof. Nicholas Knight, A.M., Ph.D.; Prof. Cyril Krauz; Prof. Marius Rebek, Ph.D." As the body is "International" in its title, it is perhaps not surprising that only one of these names appears in the "Universities Year-Book" which includes members of staffs of all the universities of the British Empire, namely, that of Prof. Hunter, who occupies the chair of chemistry in the Aligarh Muslim University, Aligarh. The president himself does not appear in the "Year-Book", but we believe he has associations with Cornell College, which is at Mount Vernon, Iowa, affiliated with the Methodist Episcopal Church, and not in any way to be confused with the great Cornell University at Ithaca, New York.

A "College" in an Office

IN addition to his association with the International Faculty of Sciences, H. W. Blood Ryan is also honorary director of the College of Pestology. We referred to that institution so long ago as December 12, 1925, when we pointed out that it is a propagandist body and not an educational institution. The "College" has a registered office at 52 Bedford Square, London, W.C.1; but though it seems to be concerned mainly with insect pests, not a single entomologist of eminence or authority is included in the list of political and other public people whose names appear upon its publications. There is apparently nothing to prevent any individual or group adopting the designation University or Faculty or College and inviting persons to join

such a self-styled body. We have no observations to make upon the objects and activities of the two bodies of this type referred to above, but scientific workers must themselves decide whether either a "Faculty" or "College", constituted as we have stated, merits their support.

Major E. E. Austen

MAJOR E. E. AUSTEN retired from the keepership of the Department of Entomology in the British Museum (Natural History) on October 19, when he reached the age limit of sixty-five years. After an education at Rugby School and the University of Heidelberg, he entered the service of the Trustees of the British Museum as second class assistant (now termed assistant keeper) in what was then the entomological section of the Department of Zoology on October 30, 1899, and was placed in charge of the Diptera; to this group of insects he has devoted his scientific life. The entomological section was separated from the Department of Zoology in 1913 with Dr. C. J. Gahan as the first keeper; on his retirement, Major Austen succeeded to the office on January 21, 1927. His last official act was to bring out the long wanted number on Clothes Moths and House Moths in the Natural History Museum economic series. As the blood-sucking flies are in the group studied by him, he has been brought closely into contact with tropical medicine. He was with the first expedition of the Liverpool School of Tropical Medicine to Sierra Leone in 1899, and has been a member of the council as well as vice-president of the Royal Society of Tropical Medicine and Hygiene. He has served on many committees including those on sleeping sickness, tsetse fly, and locust. He is a member of the committee of management of the Imperial Institute of Entomology. In early days a volunteer and later a territorial, he saw service in the Boer War and in the European War; in the latter he was twice mentioned in dispatches and was awarded the Distinguished Service Order. Mr. N. D. Riley succeeds Major Austen as keeper, and Mr. K. G. Blair has been appointed deputy keeper in the Department of Entomology of the Museum.

The Asiatic Society of Bengal

ALTHOUGH scientific workers in many fields are familiar with the publications of the Asiatic Society of Bengal, few, probably, are aware of the mass influence of this ancient foundation upon Indian progress. A glimpse of the long history of the Society was given by Dr. Rai Upendra Nath Brahmachari, in his presidential address in 1929, just published in the *Journal and Proceedings* (N.S., vol. 25, 1932). Founded in 1784, as the result of an appeal by Sir William Jones for the institution of a society to inquire into the history, civil and natural, the antiquities, arts, sciences and literature of Asia, and numbering amongst its early patrons Warren Hastings and Lord Cornwallis, the Asiatic Society set going inquiries of a kind which had fallen into abeyance in the India of the late eighteenth century. Its "Asiatic Researches" created so great an impression in the literary world that in 1798 a pirated edition was brought out in England, and on the Continent a French edition, "Recherches Asiatiques", appeared in Paris. So early as 1808, a year after the formation of the Geological Society of London and only eighteen years after Werner had propounded at Freiburg his doctrine of "Formations", a special committee was formed "to propose such plans and carry on such correspondence as might seem best suited to promote the Natural History, Philosophy, Medicine, improvements of the Arts and Sciences and whatever is comprehended in the general term Physics".

AT first geology and mineralogy received most attention, and the names of many distinguished workers figure amongst the early contributors—Voysey the father of Indian geology, Oldham who created the Geological Survey of India, Lambton of the Indian Survey, Schwendler one of the chief founders of the Calcutta Zoological Gardens, Falconer, Cautley, Colvin, Baker, Durand, to mention a few. Indeed there are few activities in the scientific life of India which have not been linked with the Asiatic Society, from the early ethnological survey of Col. Dalton, and the grand series of papers on the fossil mammalian fauna of the Sub-Himalayas, to the foundation of the Indian Museum and its off-shoot the Zoological Survey. The president added a note of warning about the risk of starting new scientific periodicals, the competition of which might result in the double misfortune of loss both to the new and the old, and made a plea for consideration of the possibility of concentrating upon the oldest journal of all, the *Journal of the Asiatic Society of Bengal*, with which, he considers, many of the new journals might be amalgamated profitably.

Ultra-Short Wave Radio Link across Bristol Channel

ONE of the results of the study of the mode of propagation of ultra-short electric waves has been to show that for wave-lengths of from one to about nine metres, the effective range is limited to the horizon or the optical distance for ordinary vision. While this property prevents the application of such waves for long distance radio communication, it has for some time been recognised that this range of wave-lengths would be very suitable for providing a radio link in the ordinary telephone system. This application is of particular advantage in spanning short stretches of water, such as a channel or river estuary, where the present alternative is a submarine cable or a land-line following a circuitous route. According to recent reports in the *Times* and the *Wireless World*, the Post Office Engineering Department has been investigating the possibilities of this application for some time past, and experiments have now successfully terminated in the setting-up of a radio link across the Bristol Channel. This link, which is twelve miles long, connects up the ordinary telephone land-lines at Lavernock, near Cardiff, on one side, with those at Hutton, near Weston-super-Mare, on the other. The wave-length employed is about five metres, and the transmitters and receivers are placed in separate huts at each site. The aerial

system consists of horizontal dipoles connected to the terminal apparatus by special transmission lines, and the whole equipment has been designed to work unattended, apart from periodic maintenance operations.

British Standard Specifications

THE British Standards Institution has for its principal object the co-ordination of the efforts of producers and users for the improvement, standardisation, and simplification of engineering and industrial materials. It specifies standards both of quality and of dimensions in order to assist production and distribution and to eliminate waste of time and material involved in the unnecessary variation of articles made for the same purpose. Thereby it contributes to safety as well as to efficiency in industry, as is evidenced by the recent publication of a British standard specification for the identification of chemical pipe lines. The proposed scheme, which was prepared at the joint request of the British Chemical Manufacturers' Association and the British Chemical Plant Manufacturers' Association, identifies the nature of the liquids or gases conveyed by means of coloured plates, bearing a distinctive letter or sign, which are to be placed adjacent to the control valve and at intervals along the pipe. Thus a workman can immediately ascertain whether a certain pipe conveys inflammable, explosive, toxic, or corrosive material, whether the contents are under pressure, or whether the pipe line is safe. The matter might at first sight appear to be a trivial one which could be left to the common sense of works managers; in practice, however, the proposed universal device will help to avoid the possibility of emergencies ending in tragedies.

Research on Coal and Coke

THE third annual report of the Northern Coke Research Committee records the many-sided activities of its staff working in the Armstrong College, Newcastle, on problems of the coals and cokes of the north of England. Like most organisations, the Committee now labours under restrictions imposed by the financial stringencies of the times. Apart from fundamental long-range investigations, there is an immediate need for documented information about the characteristics of commercial fuels, which is felt by anyone concerned with the rational choice and utilisation of available coals. To-day coal is no longer the unchallenged king of fuels. The tendency with all commodities is to look for products regular in supply, of high and uniform quality. In all these respects coal has displayed an inferiority against its competitors, and it is hard to see how the industry can maintain its position against its competitors by abandoning or diminishing efforts to inform itself about the properties of its wares. The Report for 1930–31 of the Department of Mining and Fuel Technology of the University of Sheffield also records a wide range of investigations connected with the winning and utilisation of coal, many of which have already been noticed in our pages.

Modern Tendencies in Bird Taxonomy

THE appearance of a fourth edition of the American Check List of Birds in 1931 has suggested to Joseph Grinnell a comparison between its contents and that of previous editions (*Auk*, Jan. 1932, p. 9). The result is a vivid picture of the tendency of modern taxonomic studies. The first edition appeared in 1886, and subsequent editions in 1895, 1910, and now the fourth in 1931. The total number of forms, species, and sub-species listed in these editions was 951, 1068, 1196, and 1420, a very considerable increase in about a working life-time. But a further examination shows that the increase is not equally distributed: the numbers of full species were 768, 799, 802 and 811, a remarkable stability of numbers during the period, less than one new species a year being described. On the other hand, the number of sub-species has mounted very greatly—183, 269, 394 and 609—and the tendency to multiply sub-species is shown most strongly in the last edition. There has been a great advance in the identification of fossil species, the numbers of which run, 46, 64, 72, and 156, but this is a very natural development, for recent years have seen intensive fossil collecting in many areas. The author's idea is that the tendency marked in the new edition is bound to grow, that interest in phylogeny and species-making are counterparts, and that the "species factory in nature is the only resort in final analysis for learning the true nature of the speciation process. More and more alert, students in the field of systematics will develop a facility and technique of discrimination scarcely to be dreamed of now." On the other hand, it is possible that the future will bring, rather than a development of description for its own sake, an association between specific or sub-specific forms and their environment so close that systematic description apart from reference to peculiarities of life-conditions will be regarded as inadequate.

Progress at Colombo Museum

THE building of a new west wing, a new isolated archæological gallery for stone remains, and a small building for the entomologists' department and reserve collections, has provided nearly 13,000 square feet of additional space for the public collections of the Colombo Museum. The exterior of the west wing conforms with the style of the older portion of the museum, and the block, which, as a photograph shows, is a very handsome structure, stands out as one of the finest buildings in Colombo. It is illustrative of the difficulties of museum lighting that although at most seasons the light is too intense for specimens and sight-seeing, during cloudy days in the monsoon period the lighting in the old building was found to be inadequate, and accordingly special provision has been made for artificial lighting from the roof and within the cases (Administration Report of the Director of the Colombo Museum for 1931). Many additions have been made to the Museum collections, but the section which still retains greatest hold upon the visitor is the collection of living animals, which contains a good selection of mammals

and birds, and to which a large new aviary has been added. Schools in and about Colombo make increasing use of this collection, and 8,127 scholars visited the Museum with their teachers during the year. Approximately 225,000 people entered the Museum in 1931, amongst which there were three times as many 'strangers' as European residents.

Work of the Meteorological Office

The Annual Report of the Director of the Meteorological Office for the year ended March 31, 1932 (London: H.M. Stationery Office. 1*s*. net.), deals with the seventy-seventh year of the Meteorological Office. Although the work has continued on the main lines followed in recent years, this year has seen the conclusion of a scheme of re-organisation of the arrangements made at the London headquarters for the preparation of weather forecasts. Under the revised arrangements a single branch only is concerned with forecasts, whereas formerly forecasts for aviation were done by one branch and all other forecasts by another—an awkward arrangement involving a certain amount of duplication, and one which is not justified by any essential difference between the two types of forecast. This internal re-organisation has had its counterpart in a simplification of the exchange of weather information by wireless telegraphy between different countries. This year has also seen the commencement of a scheme of co-operation with the Automobile Association in the supply of meteorological information, including forecasts, to private persons flying their own aeroplanes. The only other work of an exceptional character was in connexion with the second International Polar Year. A number of countries, including Great Britain, are co-operating in obtaining data from high latitudes for the study of meteorology and terrestrial magnetism, and are organising expeditions for that purpose. The share allotted to the Meteorological Office consists of an expedition to Fort Rae, in Canada.

Warfare on Eddystone Island

A communication received from Mr. R. A. Lover of Tulagi, British Solomons, referring to a Research Item in Nature of June 11, p. 872, based on a paper by Mr. A. M. Hocart on warfare in Eddystone Island of the Solomons (*J. Roy. Anthrop. Inst.*, vol. 61, pt. 2) points out that the only weapons to be seen now among the islanders are light spears and bows and arrows for shooting fish and small birds, while head-hunting, murder and adultery, to which Mr. Hocart had referred as the causes of strife, have long been dealt with under the British protectorate, as in all other parts of the globe where we have any share in the government. In fairness to Mr. Hocart, it must be pointed out that the brief paragraph in our columns summarises a paper of 24 pages. Reference to Mr. Hocart's complete paper will show that he was dealing with conditions in the island when he visited it in 1908–9, and further, that in describing as a whole this aspect of native culture, he covered practices which were obsolete, or had fallen into disuse not long before his visit, as well as customs which he himself observed or of which he was informed. At times, both in his own narrative and in that of his informants, he makes use of the historic present, but the context makes it clear whether he intends a reference to what was then current or to what had become obsolete.

The New York Aquarium

The most noteworthy event at the Aquarium of the New York Zoological Society, recorded in the Director's Report for 1931, was the establishment and opening of a new department for the exhibition of the smaller fresh-water tropical fishes. At the opening in December, 120 species of diminutive fresh-water fishes from many distant tropical localities were shown, and since many of these are suitable for keeping in home aquaria, part of the exhibit was a demonstration tank showing a balanced aquarium of mixed fishes suitable for such a purpose. The thoroughness with which the world is combed for the stocking of the tropical fresh-water tanks is well illustrated by a map showing collecting grounds in 43 localities, ranging from the Americas to Africa, India, Malaya, and Australia. Only one European locality, in Spain, has contributed to the tropical collection and only one to the collection of temperate fishes. An interesting activity of the Aquarium is the distribution from the hatchery of quantities of fish eggs and young fishes at different stages of development to high schools for biological studies. In addition to the year's grant of 76,167 dollars, the City of New York voted 245 dollars towards salaries for temporary labour and 1,000 dollars for the hiring of labourers for 200 days at 5 dollars a day, thereby helping to relieve the condition of unemployment. The Zoological Society provided from its own funds an additional 22,761 dollars. In the course of the year the Aquarium was visited by 2,453,806 persons.

Destruction of Hawks in the United States

It is remarkable that the many ornithological associations in the United States were unable for thirteen years to prevent the State-encouraged slaughter of hawks in Maryland. In a short article in the *Condor* (1932, p. 187), Prof. A. Brazier Howell gives some indication of what the bounty payment of 50 cents for each hawk (the law was intended to apply to the sharp-shinned and Cooper's hawks only) meant to the hawk population and to the public purse. From a total of 7 individuals killed in 1918, the year of the passing of the anti-hawk legislation, the annual slaughter reached 20,081 in 1923–24, and 22,283 in 1929–30, when the bounty was repealed. In all, during the thirteen years when the bounty was in force, 62,543 dollars were paid for 125,086 hawks. Unfortunately, the effect spread far beyond the bounds for which the Maryland legislators were responsible, for the inducement of the bounty led individuals to make a profitable business of hawk-hunting, particularly during autumn, when thousands of migrating hawks remain for short periods on passage. In the five years 1926–1930, a well-known

resting ground of such migrants furnished 40,003 hawks, or 55 per cent of the total kill during that period, and a single hawk-hunter was rewarded in 1930 to the tune of 900 dollars. It was against much opposition that Mr. E. Le Compte, the State game warden, finally succeeded in inducing the legislature to withdraw the bounty.

A Capsid Bug New in Britain

IN the *Entomologist's Monthly Magazine* for August 1932, Mr. W. E. China, of the British Museum (Natural History), discusses the occurrence of large numbers of a very small capsid on apple trees in a nursery near Chertsey, Surrey. The species *Campylomma nicolasi* Put. and Reut. is an inhabitant of the Mediterranean region and its appearance in Surrey in large numbers is of special interest. The genus *Campylomma* contains ten palæarctic species but none has previously been found in Britain. It seems unlikely that the species *C. nicolasi* is an indigenous insect, since it could scarcely have been overlooked in so well-worked a county as Surrey. Mr. China is of opinion that it is more likely to have been introduced with some Mediterranean plant, since the eggs of the family Capsidæ are almost invariably inserted into plant tissues. Whether a southern insect of this kind will survive the English climate seems questionable: the description and figure given by him will enable it to be identified should it be found again in subsequent years.

South London Entomological and Natural History Society

THE *Proceedings of the South London Entomological and Natural History Society* for 1931–32 forms the record of its sixteenth year of existence and contains several articles of interest to students of insects. Mention may be made of the contribution of Mr. A. E. Tonge, dealing with the characters of the eggs of British noctuid moths. The eggs of a large number of the species have been examined by him and briefly described and a proportion of them figured in four excellent photographic plates. Dr. E. A. Cockayne describes the larva of *Dysstroma concinnata*, and Mr. C. N. Hawkins discusses the pupæ in that genus. Among other articles, Mrs. K. Grant's account of aquatic Hymenoptera and Mr H. J. Turner's discussion on the classification of the British plume moths are also noteworthy. The volume is well produced and fully indexed, and may be obtained at the Society's rooms in Hibernia Chambers, London Bridge, S.E., price 12*s*. 6*d*.

Congress of Polish Physicists

THE sixth Congress of Polish Physicists was held in Warsaw on September 29–October 1, under the presidency of Prof. Ladislas Natanson, professor in the Jagellonian University, Cracow. The president, in his introductory address, spoke on "James Clerk Maxwell's Childhood and Boyhood". The principal subjects chosen for discussion included: the fortunes and misfortunes of physical theories, the polarisation of dielectrics, the physical interpretation of quantum mechanics, problems of nuclear physics, the connexion of physical science with engineering, general relativity, theory of band spectra, teaching of physics, etc., the chief contributors being Profs. Rubinowicz, Zakrzowski, Bialobrzeski, Wertenstein, Wolfke, Weyssenhoff, Patkowski, and others. Prof. Malarski, of Lwow (Leopol), dealt with "Maryan Smoluchowski's Life and Work". More than 120 miscellaneous papers were also presented. The Congress was decidedly successful, about three hundred members taking part in the proceedings. The next Congress will be held in Cracow in 1934.

Engineers' German Circle

THE Engineers' German Circle (Deutscher Ingenieurzirkel in London) was formed in 1931, with the joint support of the Institution of Mechanical Engineers, London, and of the Verein deutscher Ingenieure, Berlin, to further the study of technical German, to give opportunities of hearing lectures in German by eminent German-speaking technical men, and to bring together engineers interested in Continental technical developments. Meetings are held at the Institution of Mechanical Engineers about once every four weeks during the sessions, on Mondays at 6 P.M. Members meet for tea and social intercourse from 5.15 P.M. Lectures are, so far as possible, illustrated with lantern slides, in order to help members to understand better the technical terms involved; and as a rule, they last about forty minutes, which allows time for a short discussion in German to follow. The lecturers are asked to use simple language and to speak slowly for the benefit of those not very familiar with German. The present session opened on Oct. 10. The subscription to the Circle is 5*s*. a year, and the Secretary is Mr. H. P. Spratt, Science Museum, London, S.W.7.

Researches in Wood Preservation

IN addition to some useful notes on timber-treating plants in the British Isles, and on the preservation of timber investigations being carried out at research institutes and forest products laboratories, vol. 2 of the *Journal of the British Wood Preserving Association* includes some interesting papers read before meetings of the Association during the year, accompanied by valuable discussions both from the point of view of the expert and the practical commercial man. Amongst these are "The Structure of Wood", by L. Chalk; "Recent Developments in Wood Preservation", by H. Fergusson; and a general discussion on the fire-proofing of timber. Other interesting material was afforded by the papers on "The Preservation of Mining Timber on the Witwatersrand", by H. A. Read; "Experiments on Wood Preservation in the Sea", by J. H. Orton; and "Wood Structure and Penetration of Preservatives", by F. J. Popham. In an editorial note it is stated that the steady growth of the Association continues. The exhibits at agricultural shows and the lectures given by the Secretary to the various clubs and scientific associations in many parts of the country bring the merits of scientific wood preservation before a large public. Inquiries from abroad have increased, particularly from the Colonies,

and the Secretary is now in direct touch with a large number of timber users and research workers throughout the world.

Psychology of Delinquency

"STUDIES IN THE PSYCHOLOGY OF DELINQUENCY", by Grace W. Pailthorpe (Medical Research Council, Special Report Series. No. 170), represents the result of five years work on the psychology of inmates of prisons and of preventive and rescue homes. The investigation aims at finding out what treatment would lead to a restoration of these people to the ranks of the normal. It is necessary to note that a criminal is not necessarily quite different from other people; he has been found out. Dr. Pailthorpe gives details of an investigation of 200 subjects, 100 in prisons and 100 in homes. The subjects were tested for intelligence, and classified accordingly, as normal, sub-normal, and defective. The prison group proved to have a higher proportion of normals. It is not infrequently asserted that prison people are defective in intelligence: some certainly are, but some are not. They were also interviewed, and classified according to their emotional attitudes. This part of the report is excellent and the detailed case histories are very valuable. It seems obvious on reading them that our present alternatives in dealing with criminals are hopelessly inadequate and wasteful of money as well as of the human material. A large number show clear signs of mental lack of balance, and it should be part of an enlightened society's work to try to find out the cause. Hence the writer makes a plea for a study of the mentality of the criminal as well as of the crime, and discusses various alternative methods of treatment, including segregation, permanent supervision, education and psychotherapy. Many of the prisoners are really mentally sick, and if there were legal recognition of these conditions some murders might be prevented. In an appendix there is an account of some prison systems abroad.

Announcements

PROF. J. A. CROWTHER, professor of physics in the University of Reading since 1924, has been elected honorary secretary of the Institute of Physics, in succession to Prof. A. O. Rankine.

REFERRING to Prof. P. G. H. Boswell's letter in NATURE of August 13 on the subject of the age of the Oldoway skeleton, Dr. L. S. B. Leakey writes to say that he is returning to England at the end of December, and hopes then to be able to place the whole evidence against Prof. Boswell's conclusions before scientific investigators.

THE first Hinchley Memorial Lecture of the Institution of Chemical Engineers will be delivered at the Institution of Civil Engineers, Great George Street, Westminster, S.W.1, by Mr. H. T. Tizard, on October 28, at 6.30 P.M. The subject of Mr. Tizard's lecture will be "Chemical Engineering and the Aircraft Industry".

THE Lord President of the Council has appointed Prof. A. Fowler and Sir Clement Hindley to be members of the Advisory Council to the Committee of the Privy Council for Scientific and Industrial Research in succession to Sir Alfred Ewing and Sir David Milne-Watson, who have retired on completion of their terms of office. The Lord President of the Council has also appointed Brigadier-General Sir Harold Hartley to be chairman of the Fuel Research Board, and Dr. N. V. Sidgwick to be chairman of the Chemistry Research Board of the Department of Scientific and Industrial Research, in succession to the late Sir Richard Threlfall.

THE eighth volume (Pt. 2, Science Section) of the Allahabad Univ. Studies (1932) contains half a dozen papers from the Department of Zoology, five from that of Chemistry and one each from the Departments of Botany and Physics. In the first group it is natural that the work of the head of the department (Prof. Bhattacharya) should be reflected in the investigations of his pupils and two of the papers are on the Golgi bodies and other cytoplasmic structures in the eggs of Indian snakes and of the crab, *Scylla serrata*. Other papers record the congenital absence of limbs in tortoises, the structure of the gonad in a hen-feathered cock, and a number of new species of trematodes. Of the chemical papers, that on the formation of inorganic jellies may be noted.

MESSRS. NEGRETTI AND ZAMBRA have placed on the market a portable sampling hygrometer adapted for the measurement of the hygrometric conditions inside bundles of fabric, wool, fibres, etc. The instrument is of the hair hygrometer type fitted with a tube through which a sample of air is withdrawn from the bundle and circulated through the hygrometer case, which is completely air-tight except for the inlet and outlet air connexions.

APPLICATIONS are invited for the following appointments, on or before the dates mentioned:—A research student in the Institute of Pathology and Research at St. Mary's Hospital, Paddington, W.2—The Secretary (Oct. 24). An assistant lecturer in mathematics at the Technical College, Cardiff—The Director of Education, City Hall, Cardiff (Oct. 29). A junior lecturer in the Department of Pathology at the University of Liverpool—The Registrar (Oct. 31). An assistant lands officer in the Works and Buildings Directorate of the Air Ministry—The Secretary (S.2), Air Ministry, Adastral House, Kingsway, W.C.2 (Nov. 1). An assistant lecturer in metallurgy at the University of Leeds—The Registrar (Nov. 7). A part-time instructor of economics and economic history at the Kingston-upon-Thames Technical College—The Principal. A teacher of elementary science, including biology, and a mistress to teach geography, at the Medway Technical College, Day Technical School for Girls, Chatham—The District Education Officer, 15, New Road Avenue, Chatham. A valve physicist and designer at the Murphy Radio Laboratories, Welwyn Garden City, Herts.

Supplement to NATURE

No. 3286 OCTOBER 22, 1932

Reviews

Mary Kingsley

The Life of Mary Kingsley. By Stephen Gwynn. Pp. viii + 272 + 2 plates. (London: Macmillan and Co., Ltd., 1932.) 12*s.* 6*d.* net.

IN the last eight years of her too-short life, Mary Kingsley crowded many experiences. Until the age of thirty she lived a life of domestic seclusion, fifteen years being devoted to the care of an invalid mother and a delicate brother, while at the same time she assisted her father in the preparation of a work, never completed, on native law and religion. When in 1892 the death of her father and mother within a few weeks of one another left her free to follow her own bent, she set out on her travels, her choice of West Africa being determined largely by a desire to collect first-hand information for the continuation of the work upon which she had been engaged with her father. It is a testimony to the strength of her character, also, perhaps, to its peculiar quality, that notwithstanding her previous sheltered existence, she could adapt herself to West Coast society of the 'nineties—a society of traders and ships' captains which held itself aloof from the official element—and was proud to be of its fellowship, and could steel herself to the dangers of travel in the forest, alone, unescorted and unarmed, with members of cannibal tribes for her guides and carriers, among villages in which the chances were much less than even that she and her party would meet with a friendly welcome.

Mr. Stephen Gwynn's "Life", save for a few deft touches from personal recollection, leaves the sketching of Mary Kingsley's character in the main to herself. By a skilful selection from her "Travels", lectures and letters—many of the letters, unfortunately, have vanished—there emerges a detailed portrait of a remarkable personality, a personality which combined the zest for adventure and the spirit of a sixteenth century English seaman-explorer with a passion for justice and honour in dealings between governors and governed, whether the latter were the traders, who, as she saw it, were doing a great work for England and, given favourable conditions, might do more, or the natives of Britain's dependencies and protectorates. But with all her sympathetic understanding of those on whose behalf she fought, she was no sentimentalist. Both trader and native she saw as they were, and without illusion, even as, on the other side, she was always ready to do justice to the merits of her opponents; and next to this passion for justice, in the picture as Mr. Gwynn composes it, comes her genius for humour, impish and unconventional, with which she so often veiled her seriousness of purpose and almost missionary zeal.

When Mary Kingsley left England for South Africa, where she died in 1900 while nursing Boer prisoners of war, she carried with her a sense of defeat. In 1898 her projected third journey to West Africa was abandoned, as it proved for ever, in order to carry on a campaign on behalf of what she held to be the interests of both England and West Africa. In this she felt that she had failed, even though she had been consulted privately by Mr. Joseph Chamberlain, then in charge of the Colonial Office.

On the publication of her "Travels in West Africa" Mary Kingsley had involved herself in replies to critics of her views on native customs and beliefs, on missionaries and on the supply of intoxicating liquor to natives; but the development of international affairs in Africa, in which the future of the Niger Company with Sir Charles Goldie at its head was implicated, and the serious unrest among the natives which arose as a result of the imposition of the Sierra Leone hut-tax, raised issues which to her were even more vital.

Mr. Gwynn briefly, but adequately, sketches the course of relations between England and France in West Africa at this time in so far as they affected Mary Kingsley's hopes for British expansion and the development of British commercial interests in tropical Africa; but this is a matter of history. What is still a vital issue, although thanks to Lord Lugard its recognition has been won in West Africa, is the principle upon which she took her stand in the native question, namely, that native institutions should be

recognised in the relations between the administration and the native. She pointed out that the imposition of the hut-tax was a violation of treaty rights because it conflicted with native ideas of ownership of property which had not been affected by the treaties. On the general question she stated her position quite clearly. In her "West African Studies" she said (pp. 331–2) :—"I hold that one of the most awful crimes one nation can commit on another is destroying the image of justice, which in an institution is represented more truly to the people by whom the institution has been developed than in any alien institution of Justice ; it is a thing adapted to its environment. This form of murder by a nation I see being done in the destruction of what is good in the laws and institutions of native races."

On the other hand, she was equally clear in her recognition of the right or duty of the governing race to suppress, if necessary by force, practices which were repugnant to the more advanced conception of civilisation.

Mary Kingsley had a distrust of theoretical anthropologists, just as she had of stay-at-home administrators and philanthropists ; but it is evident that she appreciated anthropological work in the field in its bearing on the problems of government as providing a basis of understanding of native institutions and of the native attitude of mind towards administrative action affecting those institutions. It would be a mistake to exaggerate the part played by her ; but the interval of thirty years which has elapsed since her death has given perspective. Her work by no means failed so completely in its effect as she feared. This she would have recognised had she known that within a few years of her death, the Government of Southern Nigeria was to appoint experimentally a government ethnologist, paving the way to the work of such officials as Rattray, Talbot, Meek and others in preparation for, or as a concomitant of, a system of administration in which native institutions and native rulers play a recognised part. But progress is slow and acceptance of the principle is not even yet general.

What generations of anthropologists have urged upon the governments of their day, what individual administrators, not only in Mary Kingsley's time but also before, had realised as the result of their experience, it has taken the driving force of a Lord Lugard in West Africa and a Sir Hubert Murray in Papua to bring into actual operation. Incredible as it may seem, in some areas it is still possible for those responsible for administration—and this applies also to mission work—to say in all seriousness that their subordinates "have not the time" to study and observe the natives in their charge.

The Human Factor in Industry

Ten Years of Industrial Psychology : an Account of the First Decade of the National Institute of Industrial Psychology. By Henry J. Welch and Charles S. Myers. Pp. ix + 146 + 9 plates. (London : Sir Isaac Pitman and Sons, Ltd., 1932.) 6*s*. net.

ONE of the difficulties which besets the investigator of the human factor in industry is the relative length of time which is frequently necessary before sound deductions can be drawn from his experimental investigations and observations. The application of scientific methods to investigation of industrial problems in which the human element is a principal factor is a departure in Great Britain which is almost if not exclusively confined to the post-War decade. In this field the formation in 1920 of the National Institute of Industrial Psychology is an outstanding feature, and this very readable account of its activities during its first decade contributed by H. J. Welch, chairman and honorary treasurer of the Institute and Dr. C. S. Myers, its principal, contains abundant material for justifying the initiation of this important experiment. The Institute has already become a living and growing organisation rich in experience and fruitful in services rendered, to which we can look with confidence for assistance in the solution of many serious problems in our industrial and social life.

The Institute was formed specifically for the determination and application of psychological and physiological principles and methods in the solution of the human problems of industry and commerce, and from the outset it was stressed that its work should be scientific and not for profit. The investigation and improvement of actual working conditions and methods in factories, offices, etc. ; the study of personnel organisation, including methods of selecting staff, training, promotion, incentives, etc. ; and the giving of vocational guidance based on the physiological and psychological study of abilities and of temperamental qualities, were methods adopted by the Institute from the start, and within its first two years all the main lines of its present activities

were being actively developed, including its important educational work, courses of lectures, etc.

The survey of ten years' work as presented in the volume under review, affords sufficient material for enabling some reasoned judgment to be formed of the value of the contribution of science in this field and the developments to be expected. Certain aspects of the Institute's work have indeed earned high praise in many quarters but this summary of its activities demonstrates very clearly how closely many of them are related. Vocational guidance and selection are two aspects of one problem and in turn are closely related to problems of industrial safety and efficiency, while the wide practice of vocational guidance and selection is in turn dependent upon the success of the Institute's educational activities.

The Institute has already become the acknowledged headquarters of research in vocational guidance and selection, and despite the increased difficulty of work in this field due to the magnitude of the unemployment problem to-day, there is no sphere of its work which is of wider importance. In the difficulty of finding posts for boys or girls leaving school, the importance of finding the right post is liable to be overlooked. The experience already gained by the Institute has demonstrated not only the extent to which misfits are a source of inefficiency and accidents in industry but also the positive contribution which vocational guidance and selection can make from the point of view of both employer and employee. On one hand, it enables the employer to secure the type of worker best fitted for the positions he has to fill. On the other hand, it tends to prevent that drifting from one unsuitable position to another which has so demoralising an influence on the adolescent and tends to aggravate that gravest aspect of our unemployment problem to-day, the creation of unemployables. It is clear that the study of these problems in a scientific spirit is of vital importance, and if at the present time it is not always possible to direct the boy or girl leaving school into the ideal occupations for individual talents, the risk of a serious and demoralising misfit can be greatly minimised.

The Institute has as yet only been able to touch the fringe of this problem. Its results need application on a far greater scale and its methods and investigations need extending to all parts of the country and to all classes of occupations, including in these days of educational economy, the selection for higher education of those best fitted to profit by it. The absence of adequate vocational guidance is lamentably plain and the contrast between the careers of those entering industry unguided and those whose selection of a career is based on scientific guidance is so significant that, even in these days of stringent economy, the nation cannot afford indefinitely to incur this unnecessary waste, or to ignore the risk that anxiety at the present moment to secure any position may result in a succession of demoralising misfits and an increase in the unemployables.

The work of the Institute in this field is typical of the preventive as contrasted with remedial methods which characterise the penetration of science into any field of human endeavour. This aspect, far more than the mere raising of industrial efficiency, is the most impressive, and the better health, less fatigue and greater capacity of the worker to enjoy his leisure hours which have resulted from the Institute's industrial and commercial investigations, should be sufficient answer to those who at the present time might have objected to the simultaneous raising of the efficiency of industrial processes or operations as liable to increase unemployment. Investigations on fatigue, lighting, ventilation, noise, physiology of work, and numerous applications of psychology have demonstrated that the elimination of waste of effort, and the reduction of needless physical and mental strain which scientific thought can thus effect, hold benefits even more important to the community than are the financial benefits to industry. This contribution has hitherto been limited largely to the production side of industry. Its extension to the distributive side of industry and commerce, and indeed to all sides of government and municipal life, as well as to the home conditions which so largely shape the health and happiness of the worker, is urgently required. The present volume should assist in rousing the wider interest and fuller support required for such expansion of the Institute's invaluable work.

R. B.

Exploring New Guinea

Across New Guinea from the Fly to the Sepik. By Ivan F. Champion. Pp. xix + 267 + 24 plates. (London: Constable and Co. Ltd., 1932.) **15s.** net.

THIS book is the simple record of a very remarkable achievement—the first crossing of New Guinea from south to north in its widest

part. From the latest maps it was evident that the sources of the greatest rivers in that island, the Fly and the Sĕpik, were not far apart, but that particular area was unexplored, as are many parts of the interior. A certain amount of information about the upper waters of the Fly was available, thanks to the work of Leo Austen and other officers of the Papuan Government, but there was a blank space on the map, and as Sir Hubert Murray, the Lieutenant-Governor of Papua, says in his introduction to Mr. Champion's work, "The crossing must be done some day, and it was unthinkable that it should be done by any but officers of the Papuan service." The ordinary routine work of that service often necessitates difficult and risky journeys into the interior, so that many of the officers have performed notable explorations which have greatly added to geographical and ethnographical knowledge, but whose exploits are for the most part unknown except to those who delve into the annual reports. Thus it is not surprising that, given the opportunity, two thoroughly efficient officers should be found to attempt the adventure here narrated with slender means and without preliminary publicity.

The leadership was entrusted to Mr. C. H. Karius, and Mr. Ivan F. Champion, who was born in Papua, was appointed his colleague. The first expedition started in December 1926 and arrived at its camp, No. 10, 615 miles up the Fly on March 31, 1927, having traversed on foot nearly a thousand miles. This was where its real work was to begin, but the carriers were by then thoroughly tired of the trip. They had carried 40lb. loads, and having carried a load they had to go back over the same track more than once and get another, with rice as practically their sole diet. Before them were ramparts of sharp brittle limestone with neither water nor soil, over which they painfully attempted to crawl, but they were forced to return. Another track over a limestone ridge was more promising, but these and other attempts of the two explorers, who tried different routes, proved abortive. An alarming feature in one district was the crashing down of mountain sides.

At Mount Blücher the party divided. Karius went north-east and reached the head of a valley that led northwards to the Sĕpik, but lack of supplies forced him to return and he followed a river that turned out to be the Strickland. Champion went north-west and traced the Luap or Palmer River to its source, and passed down the Bol to the village of Bolivip where, though the natives had never seen a white man, they were royally entertained. He then made a trip to near the source of a mysterious river, the Feneng, which afterwards proved to be the Fly, and heard of another to the north, the Takin, which Champion conjectured could be no other than the Sĕpik. The carriers were worn out and the food all but exhausted so he had to return to Mount Blücher. There, at Camp 10, they made rafts by means of which they travelled 500 miles down the Fly after many exciting adventures. In the estuary of the Fly the two parties were reunited on July 12 and they reached Port Moresby on July 17.

On September 17 the explorers left Port Moresby for a second attempt, this time taking with them 32 carriers from the d'Entrecasteaux, sturdy, hardy men, accustomed to climbing mountains, unlike the former carriers, who came from the estuary of the Fly; there were also 14 armed native constables and 26 prisoners. In due course they reached Bolivip; the natives were friendly but were greatly depressed because owing to a lean season they could not provide their visitors with an ample supply of food. After some difficulty, they persuaded the chief, Tamsimara, to conduct them to the Takin, for the Bolivip people occasionally crossed the divide to join in feasts at Feramin. They went up the Amil affluent of the Bol, and soon came to limestone walls that were most difficult to climb. Everything was saturated with moisture and the icy blasts froze the carriers; at an altitude of 8900 ft. the rain had diminished somewhat but it was still blowing and bitterly cold. The limestone country became worse and worse, rocks with razor-like edges to clamber over, chasms to cross by rotten tree trunks, they descended into large pot-holes varying from 50 yd. to 100 yd. in diameter and from 30 ft. to 100 ft. deep and had to clamber out of them. There was no water and no level ground. The highest camp was at 8300 ft.

In due time the expedition reached the divide at a height of 9000 ft., when the track began to go down, but they were enshrouded in mist and rain and no compass bearing could be made. There were still dangerous chasms to be crossed, but at last they were on a small grass plateau at a height of 7000 ft. in bright sunlight with a magnificent panorama in front of them. On a projecting rock stood Tamsimara calling out "Wok Takin!" They saw where the Takin started its flow in a narrow ravine to the east formed by two spurs of the

Victor Emanuel Range. The last days' march had been too much for the carriers, whose spirits had dropped to zero, but the leaders and the police were jubilant. "Little did they know, as we did, that it was but the commencement of our trials and tribulations." Tamsimara, who was really a remarkable person, introduced the travellers to the people of the village of Feramin, before he made a dramatic farewell. The Feramin received them kindly but had very little food to sell.

The next part of the journey was also difficult and owing to an accident Champion had a bad knee and had to be carried in a stretcher for several days, which greatly impeded their progress. They had only 11 days reduced rations left and were still in the mountains. Karius as usual remained undaunted: "he could take defeat in the matter-of-fact manner with which he met success". They had now arrived at a point where it was possible to identify features marked on German maps of the Sĕpik and at times were able to obtain sweet potatoes and sugar cane from the natives, who were friendly but had to be handled with care.

For eleven days Champion had practically lived on the stretcher, and though lame he made up his mind to attempt to walk, and managed to hobble along. There was now food only for five days and the mouth of the river was 600 miles away. Difficult mountain land had still to be traversed and rivers crossed, but on December 23, 1927, they looked upon the great inland plain and an hour later the mountain journey had ended. In a forest glade Karius came suddenly upon a village, the men rushed out fully armed with bows and arrows and drew up in a line three men deep; the quiet courage of Karius saved the situation and shouts of defiance changed into calls of welcome. Here they were able to buy 160 lb. of sago.

They had to leave the Sĕpik and travel into the hilly hinterland and were now in Netherlands New Guinea. They crossed the Hoffnungs River and came to another which proved to be the Holländer; here they made rafts but these were wrecked and lives were nearly lost. The police lost their rifles: "It hurt them more than anything could do. They accepted hunger, fatigue, and even death as a part of their work, but to return to Port Moresby without their rifles was too much." Food ran out and Karius and Champion were down with diarrhœa and fever; fortunately they were able to make sago, but a carrier, who had collapsed in the swamps, died—the only death on the expedition. Rafts were again made and they soon shot into the main river. On January 19, 1928, 500 miles up the Sĕpik they saw the *Elevala*, which had been sent from Port Moresby to meet them. "The silence was broken by the sobs and hysterical laughter of the police and carriers who madly clutched at one another, and who then, with triumphant shouts, reached for the oars." Thus ends the book.

Mr. Champion has given us a fascinating, though restrained, record of a most memorable expedition into the unknown. Travelling in the interior of New Guinea is exceptionally difficult and dangerous; food has to be carried and it must be remembered that "a carrier himself will, in a month, eat the load of rice he starts off with", so sufficient stores had to be carried inland to the point from which the final dash was to be made. Travelling in the limestone mountains was a nightmare; besides lack of food and the lurking of diseases and accidents, there were unknown natives to be placated. The Papuan service affords good training for all these emergencies and its fine tradition of dealing with natives enabled the explorers to make friends with suspicious savages even when their attitude was aggressive. The behaviour of the native police was, as usual, efficient and cheerful, and the carriers and prisoners, almost without exception, worked hard and with loyalty. Mr. Karius has well deserved the gold medal awarded to him by the Royal Geographical Society. A. C. HADDON.

Dwarf Succulents

Mesembryanthema: Descriptions, with Chapters on Cultivation and General Ecology. By Dr. N. E. Brown, Dr. A. Tischer and M. C. Karsten. Pp. xxvi + 323. (Ashford: L. Reeve and Co. Ltd., 1931.) 36*s*. net.

THE group of plants known as mesembryanthemums is almost exclusively of South African origin and contains a great diversity of growth forms. In the work under notice, attention is confined to the 'dwarf', 'stone' or 'sphaeroid' types. These are the peculiar forms localised in the Karroo and Namaqualand, where the rainfall averages 5–10 in. a year. Light intensity and day temperatures are high and the conditions generally are extremely severe. It is owing to these factors that some plants have developed the small succulent habit to such a high degree of efficiency.

For nearly two centuries, mesembryanthemums have attracted the attention of horticulturists, but owing to the specialised conditions required for successful growth, their cultivation was somewhat restricted until comparatively recently. Latterly, however, mesembryanthemums, American cacti and other dwarf succulents have been adopted by the general public, particularly on the Continent, to decorate window boxes. Miniature gardens in bowls and various other designs have also gained great popularity.

While general interest was at its height, Dr. N. E. Brown, after many years of intensive study, decided that the Linnean genus *Mesembryanthemum* should be divided into a number of smaller genera, and in 1925 commenced the publication of his views. Not long after, Dr. Schwantes, in Germany, and Mrs. L. Bolus, in South Africa, followed a similar course, and since then many articles have been published containing new genera and species. It need scarcely be added that much of the work of these authors has overlapped and considerably more than a hundred new genera have been described and the synonymy increased unnecessarily. To give examples from the work under review: *Conophytum pellucidum, Schwant.*; syn.: *C. elegans*, N. E. Br.; *Lithops Marlothii*, N. E. Br.; *Ophthalmophyllum Marlothii*, Schwant.; and another, *Bijlia cana, N. E. Br.*; syn.: *Mesembryanthemum canum*, Haw.; *M. Tugwelliæ*, L. Bol. *Juttadinteria Tugwelliæ*, Swant.; *Hereroa Tugwelliæ*, L. Bol. *Bolusanthemum Tugwelliæ*, Schwant.

The necessity for such an authoritative publication on these plants requires no further emphasis, and coming as it does at a time of wide public interest in its subject, there is no doubt it will meet a real demand. In order to make it a work of wider reference, the editor, E. J. Labarre, decided to have the text printed in English, German and Dutch. Dr. Tischer is responsible for the opening chapter on cultivation, which is followed by a chapter on ecology by Miss Karsten. To these two authors fell the task of translating the main body of the work by Brown, consisting of short descriptions of a large number of species, accompanied by excellent illustrations. Brown's care and exceptional knowledge of the group is a guarantee of accurate and useful information. The photographs, by various authors, and two coloured plates by N. E. Brown are of outstanding merit.

In the chapter on general ecology, a large number of examples of mimicry in plants is given, where the plants resemble in colour and shape the stones amongst which they grow, and the inference is that the plants have directed their evolutionary progress; but the section concludes with the very necessary warning that this aspect may not be of such importance as hitherto imagined; and that the environment, for example, light, temperature, humidity, soil, etc., working as a whole, is the directive force, is the generally accepted view of modern thought. Prominence is given to the ravages of beasts and birds, particularly of ostriches, but since the ostrich feather has fallen from women's favour, the menace has largely disappeared. On the other hand, the more recent popularity of succulents throughout the world has resulted in collectors taking even greater toll of the wild plants for commercial purposes. This brings one to the consideration of propagation and regeneration. Dr. Tischer gives a host of valuable hints on these points. The reviewer would emphasise the success which attends propagation from seed and cuttings, and if these means are more fully developed, the demand for fresh supplies from the native haunts will be lessened, and this is greatly to be desired.

"Mesembryanthema", although not claiming to be an exhaustive treatise on dwarf species, is an important work of reference, and every serious cultivator of these plants will find it indispensable.

Animal Picture Books

(3) *Nature by Night.* By Arthur R. Thompson. Pp. xiii + 144 + 44 plates. (London: Ivor Nicholson and Watson, Ltd., 1931.) 12*s.* 6*d.* net.

(4) *The Life Story of Beasts.* By Eric Fitch Daglish. Pp. x + 223 + 21 plates. (London and Toronto: J. M. Dent and Sons, Ltd., 1931.) 6*s.* net.

(5) *Fishes.* By E. G. Boulenger. Pp. 174 + 8 plates. (London: Chapman and Hall, Ltd., 1931.) 7*s.* 6*d.* net.

(1) "BEAUTY in Animals" is introduced by Friedrich Schnack and consists of sixty-four photographs, mostly by Hedda Walther. The series of pictures of mammals and birds, "is the means to assist us to find the way to a higher view,

and to sharpen our understanding for it". Many of the pictures are of parts of animals and in most of the rest the animal fills up the greater part of the picture. We have never found a series of stuffed animals to excite the emotions and we are sure that these pictures will seldom do so. Why not let the publishers try again and show the animals alive in characteristic attitudes, or better, in their natural environment as Mr. Swinton has done in his "Monsters", mostly giants of earlier days (2). Here there are accurate reproductions of models representing the animals in natural motion, set in appropriate environments so as to form pictures. They look to us like superposed photographs, in other words, ancient beasts with modern plants. We do not object to this, for the gain is great, but we think a little more attention to composition and printing would make many of the pictures less confused. The text might be made still more popular, and why give specific names to most reptiles and to no mammals?

(3) "Nature by Night" is in a higher category both of art and science, dealing with animals that have their maximum activity in the hours of darkness. The numerous pictures of living animals are beautiful. Those by flashlight have a certain absence of colour values, but are peculiarly valuable as indicating nocturnal conditions. To the badger and the rabbit they must be nearly the same and the reader should examine and compare the photographs of these two at night and in the daytime. We ask for pictures of the stoat and weasel. The whole is illuminated by an admirable text with little introduction of matter not within the author's own knowledge. Every naturalist will find this book delightful reading, well worthy of a place in his library; teachers will feel that it greatly helps them. Its production is a credit to its publishers and its price is moderate.

(4) To the more sophisticated and modern, which few naturalists are, Mr. Daglish's book should appeal for its woodcut illustrations. Those which close the chapters are delightful. Of the full page illustrations some are anatomical, such as the whale and mole, but many suggest a vigorous existence with the beast using its environment intelligently and itself well adapted to it. The text is admirable throughout and singularly free from technical terms. The arrangement into chapters dealing with the food, homes, courtship, intelligence and other characters of beasts is good. This is an excellent little book.

(5) We wonder whether we shall be criticised for classifying "Fishes" as a picture book, but we think L. E. Brightwell had great fun in making line drawings from fish in the Zoological Society's Aquarium. We like the drawings, for the fish are alive, their salient features well shown and unnecessary detail omitted. The sawfish is a partial failure, and the copies of earlier figures of the young of the eel scarcely suggest this little transparent person. The tiny male of the angler fish, fused as a parasite to the body of the female, is of peculiar interest. The weaver's poison spine is an efficient defence even against man, for it is as good eating as the sole. The text is admirable, but few people will recognise the sail-finned and reed fishes as *Polypterus* and *Calamoichthys* of African freshwaters; the latter is not even put in the index. Otherwise it is a simple account of the very diverse forms and habits of fish. We recommend this book to all readers and trust that its next edition will be published at an even lower price so as to command the widest public.

A Subantarctic Island

South Georgia, the British Empire's Subantarctic Outpost: a Synopsis of the History of the Island. By L. Harrison Matthews. Pp. xii + 163 + 26 plates. (Bristol: John Wright and Sons, Ltd.; London: Simpkin Marshall, Ltd., 1931.) 15*s*. net.

In view of the importance which South Georgia has assumed during the present century as one of the centres of the whaling industry, it is strange that no book on the island has hitherto been published. The account which Mr. Matthews gives is thus welcome, the more so since it is based on close personal acquaintance with the island and its industries.

The description of the island, with which the book opens, contains a good general account of the topography and notes on the climate and on the flora. The section on the fauna is the longest and it is here that the reader gains most from the author's first-hand knowledge. The account of the birds, seals and whales is excellently done, and even fuller treatment, especially of the courting ceremonies of the albatross, might have been given. The section on geology is less adequate, and the author is apparently unacquainted with Holtedahl's recent work.

The book, however, as the sub-title indicates, is mainly devoted to the history of the island, and

three of its six chapters deal successively with the early navigators, the sealers, and nineteenth century voyages. These chapters, which must have involved protracted research, are valuable in bringing together information from many widely scattered sources, and one feels there is little need for the apology that the author offers for the numerous quotations. Mr. Matthews has some new suggestions to make regarding the courses taken by la Rochè and Guyot, and though the sealers who followed in the track of eighteenth century exploration were reticent folk, more anxious to conceal than to advertise their movements, the collected information presents a good picture of their activities and of the ruthless methods which resulted in the virtual extermination of the fur seal.

The book concludes with an account of present-day conditions and some speculations as to future prospects. The history of modern antarctic whaling is traced from its beginnings in 1904, and the methods adopted in whaling and in taking elephant seal (South Georgia's only industries) are described. Much useful information is conveyed in an attractive form ; for it is blended with local anecdote, and while making good reading, succeeds in giving a vivid impression of life in the island. It is unfortunate that the author should quote, with evident approval, Gordon Hayes's criticisms of British territorial claims in this sector of the antarctic. Those unable to resist the temptation to decry the actions of their own government should first assure themselves that their facts are correct and the passage quoted from Hayes contains an inexcusable error.

There are many illustrations, but the omission of references to them in the text is inconvenient : a bibliography is given and a good index. For a comparatively short book the price seems high.

Photoelectricity

Photoelectric Phenomena. By Prof. A. Ll. Hughes and Prof. L. A. DuBridge. (International Series in Physics.) Pp. xii + 531. (New York: McGraw-Hill Book Co., Inc.; London: McGraw-Hill Publishing Co., Ltd., 1932.) 30s. net.

PROGRESS in the subject of photoelectricity has been so great during the past ten years that there was real need for an authoritative account of recent investigations. This need has now been supplied by the admirable volume by Profs. A. L. Hughes and L. A. DuBridge, whose book provides a concise yet comprehensive survey of this interesting field. After a short introduction, four chapters are devoted to the experimental results as to the emission of electrons from metal surfaces illuminated by visible or ultra-violet light. Chap. iii on "The Photoelectric Threshold" includes data for the work functions of the metals which should be of considerable use.

Chap. vi deals with theories of photoelectric emission, and though the authors modestly disclaim any special qualifications for dealing with theoretical problems, they have been very successful in giving an outline of this aspect of the subject. "The photoelectric effect, which has long been one of the cornerstones of the quantum theory of radiation, now finds itself closely intertwined with recent advances in quantum mechanics and the newer electron theory of metals." This chapter is divided into two main sections, the first dealing with the classical theory and the second with the Sommerfeld electron theory which has been developed by Fowler and Nordheim, Wentzel, and others. The transmission of electrons through potential barriers is one of the fundamental concepts of the new theory.

Two chapters follow, on the volume photoelectric effect, including the ionisation of gases and vapours by ultra-violet light and also photoconductivity in crystals, in partial conductors and in liquids. These contain a large amount of information not previously available in English. Photovoltaic effects and photoelectric effects in liquids and insulators are also treated.

Chaps. xii and xiii may be specially commended and should be studied by experimental physicists and by those who are concerned with the now numerous applications of photoelectricity. The former chapter is concerned with photoelectric technique and the latter with applications to photometry and to the transmission of pictures and of sound. One very striking illustration of the sensitiveness of the photoelectric method is afforded by the work of Rajewsky. Using a Geiger-Müller tube lined with a metal sensitive to the ultra-violet, the emission of single photoelectrons could be detected. Connecting the tube to an amplifier with a loud-speaker at the output end, it was possible to 'hear' the emission of each electron. The book is written in a very attractive style and is well produced.

H. S. ALLEN.

Short Reviews

Anthropology

At Home with the Savage. By J. H. Driberg. Pp. x+267+16 plates. (London: George Routledge and Sons, Ltd., 1932.) 7*s.* 6*d.* net.

MR. DRIBERG's "At Home with the Savage" is a remarkable book. It has an attractive title, it is popular in aim, and it contains nothing that the person of average intelligence should not be able to understand. Yet it is a book which has a very real significance from the point of view of science. Although the author expressly denies it the character of a textbook, it does, as a matter of fact, restate the subject matter of social anthropology from the point of view of the group of workers who study the activities of man as a member of a society in accordance with principles and methods which have come to be known as 'functional' anthropology.

A new orientation is given to the study of the peoples of the simpler cultures in which attention is diverted from questions of the origin or form of institutions and directed to consideration of how they actually work and what is their meaning and significance in a given environment. This concentration of anthropological studies on function was the subject of Prof. Radcliffe Brown's presidential address to the Anthropological Section of the British Association at its meeting last year, and has been demonstrated by Prof. Malinowski in a number of special studies; but Mr. Driberg's book is the first systematic statement of it as a whole on popular lines.

Its concrete treatment of the subject by the citation of a wealth of instances should convince the public for whom it is intended of the practical value of anthropological studies in the administration of the affairs of the native peoples of our dependencies. For this is a moral which the author never fails to point by pushing home the lesson of how difficulties may arise in these matters through the conflict of ideas as between ruler and ruled, and how they have, or might have, been avoided by a knowledge of anthropology.

It would perhaps be out of place in this notice to quarrel with Mr. Driberg for dismissing summarily branches of anthropology and methods of study other than those of his own school; yet perhaps even in support of his own point of view there might be something to say on the other side.

Tribes of the Niger Delta: their Religions and Customs. By Dr. P. Amaury Talbot. Pp. xi + 350 + 40 plates. (London: The Sheldon Press; New York and Toronto: The Macmillan Co., 1932.) 18*s.*

IN this volume Dr. Talbot describes the peoples of the Degama Division of Nigeria, who, broadly, fall into two groups—the Ibo people of the north, representing the southern-most extension of that great race, and the Ijaw, who occupy the swampy area intersected by innumerable streams along practically the whole coastal fringe, over a range of 250 miles. According to tradition, which Dr. Talbot apparently sees no reason to set aside, the whole of the latter area is sinking.

Be that as it may, the character of the environment has impressed itself very strongly on the culture of the Ijaw, which in many respects is of a markedly primitive character. One branch lives entirely by fishing and trading. These are the Kalabari, who at one time attained domination over the whole area owing to their proximity to the European slaver settlements. They now have practically a monopoly in the provision of dried fish, virtually a necessity in the dietary of the tribes. Another direction in which the influence of the environment is to be seen in a marked degree is the prominence of the water spirits in the religion of the Ijaw. The contrast with the culture of the Ibo is marked, though it is evident that there has been borrowing on the part of the latter. In his description of the customs and beliefs of the two groups, Dr. Talbot so far as possible has made use of evidence given by his native informants in practically their own words. Frequently it has been derived from his court records. This gives it an added value, especially in its revelation of the working of the native mind.

The photographs, as is usual in Dr. Talbot's books, are numerous and excellent, the subjects being chosen with a wise discrimination.

Biology

Handbuch der Pflanzenanalyse. Herausgegeben von G. Klein. Band 1: *Allgemeine Methoden der Pflanzenanalyse.* Bearbeitet von R. Brieger, F. Feigl, P. Hirsch, E. Keyssner, G. Klein, H. Kleinmann, G. Kögel, H. Lieb, H. Linser, J. Matula, L. Michælis, C. Weygand. Pp. xii + 627. (Wien und Berlin: Julius Springer, 1931.) 69 gold marks.

THE principal distinctive feature of this work is its breadth of outlook. While books on biochemical method normally give in detail the methods required for the estimation of particular substances in a plant tissue, this, while not neglecting such details, is principally concerned with the general analysis of a plant tissue or a substance, and more particularly with the principles governing the choice of methods and the principles involved in their application. Even a person moderately well acquainted with biochemistry will receive something of a shock on realising from a book of this type the extraordinary range of methods now available as aids in analysis of one form or another. Ultra-filtration and ultra-microscopy may give valuable information; fluorescence and photochemistry are also called upon for assistance and there are useful chapters on micro-methods and

histological chemical methods which should appeal especially to the general biologist.

The more familiar methods are treated in up-to-date manner and there are interesting chapters on extraction and preparation of material for analysis. A valuable feature of the book is, however, the inspiration which will come from the range of methods discussed.

Regeneration und Transplantation. Von Prof. Dr. E. Korschelt. Band 2: *Transplantation unter Berücksichtigung der Explantation, Pflanzenpfropfung und Parabiose.* Teil 1. Pp. xx + 695. (Berlin: Gebrüder Borntraeger, 1931.) 63 gold marks.

THIS is the second part of the enlarged edition of Prof. Korschelt's well-known book and deals exhaustively with the phenomena accompanying transplantation of parts or organs in plants and animals. It is an exhaustive survey of the known facts and brings together a great wealth of material from a widely scattered literature, and therefore forms an important source for all specialists.

Little or no attempt is made to deal with the philosophical significance of the experimental facts—possibly this is reserved for a later volume—but the book would have been of greater value as a textbook had points of theoretical significance been stressed at greater length at the expense of some of the descriptive data. The text and the figures are beautifully clear, and no biological library can afford to dispense with such a scholarly compilation of important work.

The phenomena of transplantation and regeneration are clearly of fundamental importance and, as in other aspects of experimental biology, new facts accumulate rapidly. It is, however, important that the literature of science should not become burdensome to students or to research workers. Whilst one hesitates to criticise the work of a distinguished author, at the same time, one cannot resist a feeling of regret that the field which Prof. Korschelt covers has been expanded so far beyond the modest dimensions of the first edition. Is it too much to hope that he will give us an abridged account of this interesting field—an account which will appeal to biologists generally and not primarily to specialists?

Elements of Water Bacteriology: with Special Reference to Sanitary Water Analysis. By Prof. S. C. Prescott and Prof. C. E. A. Winslow. Fifth edition, revised. Pp. ix + 219. (New York: John Wiley and Sons, Inc.; London: Chapman and Hall, Ltd., 1931.) 12*s.* 6*d.* net.

THE authors, in this latest edition, give a valuable and comprehensive survey of the methods which can be used for the bacteriological analysis of water, with special reference to American practice. Their desire for the unification and simplification of these methods is a reasonable one, though the difficulty of fixing an arbitrary standard, as they themselves point out, is that each sample of water must be judged individually upon the correlative evidence as well as upon the bacteriological findings. The importance they attach to the distinction between *B. aerogenes* and *B. coli* would appear to be minimised by this fact, but, where the distinction is necessary, some recent work by Taylor and Goyle in India seems to show that Eijkman's method of incubating the primary cultures at 46°C. provides a sufficiently reliable demarcation between the saprophytic and intestinal strains of coliform bacilli without lengthening the routine examination.

The authors consider, justly, that averaging results of the bacteriological examination of a series of samples taken from the same water supply over a long period, is open to criticism, since this tends to obscure any temporary, and possibly dangerous, pollution of such a supply.

The book has a useful bibliography, but there are some misprints in the bacteriological table on p. 59 which might be confusing to the inexperienced worker.

The Biochemistry of Muscle. By Dr. Dorothy Moyle Needham. (Methuen's Monographs on Biological Subjects.) Pp. viii + 166. (London: Methuen and Co., Ltd., 1932.) 5*s.* net.

THE author of this monograph has clearly been handicapped by the extent of the published work that she has had to survey. To achieve this adequately she has been compelled to do nothing more than very curtly define the highly specialised terminology of the branch of biochemistry discussed, and this makes the book difficult to read for all those not actually engaged in the field. This unavoidable defect is, however, far more than balanced by the comprehensive nature of the treatment in an astonishingly short space. To have reviewed in 140 pages the voluminous researches of Hill, Embden, Meyerhof and their colleagues, with a bibliography of three hundred references, and an index, and to have reviewed it critically and comprehensively, is something for which many biochemists will be profoundly grateful, and to have given them this cause for gratitude at so low a price is a credit to the publishers.

Chemistry

Recent Advances in Analytical Chemistry. Vol. 2: *Inorganic Chemistry.* Editor: Dr. C. Ainsworth Mitchell. Contributors: Norman Evers, B. S. Evans, S. G. Clarke, W. R. Schoeller, A. T. Etheridge, Brynmor Jones, A. R. Powell, Janet Warden Brown, J. W. Haigh Johnson. Pp. xiv + 452. (London: J. and A. Churchill, 1931.) 15*s.*

IN addition to chapters recording recent work on the analytical chemistry of the elements, the volume includes chapters on the determination of hydrogen ion concentration and on potentiometric titrations, on microchemistry and on water and sewage analysis.

On the ground of economy of space, working details of new methods of analysis of the commoner elements are not given; these chapters are written on a plan very similar to that adopted in the Chemical Society's Annual Reports. This procedure has a defect: it does not afford the reader much guidance for selecting a method best adapted to particular circumstances. On the other hand, the chapters on the rarer elements, particularly those on selenium, tellurium and the acid earths, give adequate descriptions of the newest methods of their separation and determination. Space has been found for short but useful chapters describing the determination of gases in steel and the examination of graphites and carbon blacks.

The first chapter in the volume gives a good survey of modern methods of the determination of hydrogen ion concentration and of potentiometric titrations and includes a description of the glass electrode, which has been found to be so useful industrially. Microchemical methods are described in some detail with references to the use of coloured and impregnated threads and to 'spot' tests. Nephelometry receives less space than is due to its importance in biochemistry. There is a general discussion on the difficulties encountered in the problem of the determination of pollution in waters, and the shortcomings of the existing methods of analysis are indicated.

The book is well printed and assembled, free from errors, and has a good index. It should be on the shelves of all chemical libraries.

Lunge and Keane's Technical Methods of Chemical Analysis. Second edition. Edited by Dr. Charles A. Keane and Dr. P. C. L. Thorne. Vol. 3. Pp. xx + 678. (London and Edinburgh: Gurney and Jackson, 1931.) 63*s*. net.

THIS volume is a collection of treatises by well-known authors on clays, glass, cement, water, sewage and effluents, fertilisers, feeding stuffs, soils and air. Since the date of the publication of the previous edition (1908), so many improvements have been made in technical methods of analysis that the subject matter of the earlier volume has been much increased and largely rewritten. In the present volume the examination of clays is divided into two parts, chemical and physical, each with a separate author, an arrangement which reflects the increasing importance attached to their physical characters.

The methods of analysis described are representative of modern analytical procedure and, generally, little criticism is necessary. Among the methods used for the colorimetric determination of iron, no mention is made of the thioglycollic acid method, which is both delicate and independent of the state of oxidation of the iron. But it is gratifying to note that the very convenient method of titration of iron by means of titanous chloride is advocated.

Included in the section on air are the results of recent research on the gaseous impurities of the atmosphere of towns, including carbon monoxide, oxides of nitrogen and the acid oxides of sulphur. Subsequent work on the Government Laboratory method for the determination of the acid oxides of sulphur (p. 628) has shown that with a suitable indicator the method affords a reliable measure of these oxides in the air; in the absence of fog they have been found to be composed almost entirely of sulphur dioxide. A. G. F.

Handbook of Chemical Microscopy. By Prof. E. M. Chamot and Prof. C. W. Mason. Vol. 2: *Chemical Methods and Inorganic Qualitative Analysis.* Pp. ix + 411. (New York: John Wiley and Sons, Inc.; London: Chapman and Hall, Ltd., 1931.) 22*s*. 6*d*. net.

THIS volume describes the manipulative methods of chemical microscopy; it is a compilation of reliable tests for inorganic cations and anions. In Chapters i and ii general and special manipulations are given in detail and special apparatus is illustrated. It may be noted that some of the apparatus needed for the manipulation of gases and volatile liquids shows a general resemblance to that used by Faraday in his 'minute' chemistry.

The next nine chapters contain detailed tests for the detection of the elements arranged in the groups of the periodic table and also for many inorganic anions. The reactions are well chosen and in many cases have stood the test of time, being those of Behrens, to whom the authors acknowledge their indebtedness. Many beautiful reproductions of photomicrographs of crystals are given and these increase the usefulness of the work; the authors, however, are careful to state that the illustrations must not take the place of the direct study of the tests.

Chapter xii describes the use of some special reagents and the separation of metals based upon their differences of electric potential. A scheme for the qualitative analysis of materials of unknown composition, including alloys, forms the last chapter of the book, which is completed by the addition of an appendix giving details of the preparation of the special reagents, and a good index.

Geology

German-English Geological Terminology: an Introduction to German and English Terms used in Geology, including Mineralogy, Petrology, Mineral Deposits, etc. By Dr. Arnold Cissarz and Dr. William R. Jones. Pp. xvii + 250. (London: Thomas Murby and Co.; Leipzig: Max Weg; New York: D. Van Nostrand Co., 1931.) 12*s*. 6*d*. net.

THIS work is intended for those who have already acquired some knowledge of German (or English), but are not familiar with German equivalents of the special terms used in the various branches of geology. The book is arranged on the lines of an elementary textbook and is bilingual. All scientific terms are italicised when first used. Equivalent

portions of the text are arranged on opposite pages, and corresponding paragraphs represent close translations one of the other. Literary style has been subordinated to the necessity for maintaining as nearly literal a relationship as possible between the English and German texts. Four appendices deal with abbreviations used in geological literature, English and German weights and measures, the chemical elements, and mineral names.

As a general criticism it may be suggested that the text is somewhat unbalanced with regard to the amount of space allotted to each of the several branches of geology. Thus, palæontology is represented solely by a chapter containing formal descriptions of the various groups of invertebrate fossils, while vertebrate palæontology and palæobotany are ignored. The principles of stratigraphy are dismissed in a single page. On the other hand, petrology, mineralogy, crystallography and allied subjects receive detailed treatment.

Some terms one would expect to have been included have been omitted, and a few spelling errors were noticed. As a whole the book can be recommended for the use of students. A mastery of its contents should adequately if not completely equip those who wish to read geological literature in the original German. V. A. E.

A Key to Mineral Groups, Species and Varieties. By Dr. E. S. Simpson. Pp. viii + 84. (London: Chapman and Hall, Ltd., 1932.) 10*s.* 6*d.* net.

It has always seemed a matter for regret that so many of the names applied to mineral species, even in recent years, give no indication whatever of the chemical composition or physical properties of the mineral. Instead of attempting to clarify the science by devising a self-explanatory system of nomenclature, mineralogists continue to increase the tax on their memories by attaching to new minerals quite irrational names. This being the case, Dr. Simpson justifiably claims that his tables may be regarded as a *vade mecum* to everyone interested in minerals. He has listed in alphabetical order upwards of 1800 mineral names. Opposite each mineral is stated concisely its chemical composition, specific gravity, crystal system and refractive indices. These data have been collected from the latest and most accurate sources available. In addition, reference is given in every case to a source of detailed information regarding each mineral. The latter item is particularly valuable in the case of the newer mineral species, about which data have, until now, remained scattered through many publications.

The literature of mineralogy is cumbered with a great number of useless names. The list is selective to the extent that the author has omitted names which he regards as obsolescent or which stand only for minute differences in unessential characteristics.

The tables represent a careful compilation by the author of information gathered from many sources over a long period of years. Dr. Simpson is to be congratulated on having made accessible to the public in such concise form the result of his labours.

The Microscopic Characters of Artificial Inorganic Solid Substances or Artificial Minerals. By Prof. A. N. Winchell. With a Chapter on the Universal Stage, by Prof. R. C. Emmons. Second edition. Pp. xvii + 403. (New York: John Wiley and Sons, Inc.; London: Chapman and Hall, Ltd., 1931.) 31*s.* net.

Formerly known as "The Optic and Microscopic Characters of Artificial Minerals", the modification in the title of the new edition of this work serves to prevent misapprehension as to its scope. This is, in fact, much wider than would be the case if it dealt only with synthetic *minerals*, using the latter term in its generally accepted sense. The author has attempted to include all inorganic substances the optical constants of which are known.

Many changes have been made since the first edition appeared (Nature, vol. 122, p. 436, 1928). The book is now cloth bound, and has been greatly enlarged, chiefly through the introduction of a new section on optical principles and the methods of study of crystals under the microscope. This, Part I of the new edition, consists largely of revised selections from the same author's "Elements of Optical Mineralogy", Part I, third edition (see Nature, vol. 123, p. 158, 1929), and includes a chapter on the universal stage. Numerous alterations and additions have been made in the descriptive section of the book, and the determinative tables have been re-written and re-arranged.

The new section obviates the necessity for reference to other textbooks for those not familiar with the microscopic study of crystals and renders the book to a large extent self-contained. Altogether the new edition is a great improvement on the old.

Mathematical and Physical Science

Dielectric Constant and Molecular Structure. By Prof. C. P. Smyth. (American Chemical Society Monograph Series, No. 55.) Pp. 214. (New York: The Chemical Catalog Co. Inc., 1931.) 4 dollars.

This book effectively completes Debye's "Polar Molecules" and Errera's "Polarisation Diélectrique" by a detailed account of the subject in its relation to chemical constitution. Electrically polar molecules, its principal concern, have never been of so much importance in physics as the formally similar magnetic dipoles or as non-polar molecules, but the advent of thermionic valve methods for finding the dielectric constant opened up a wide field for their application in chemistry, development of which is due in no small degree to Prof. Smyth.

The subject matter falls roughly under three heads. The first three chapters are upon the elementary theory and the measurement of the

dielectric constant. The mathematics is not taken very far, but is adequate for the purpose of the monograph, whilst the account of experimental methods gains by Prof. Smyth's personal experience. The second and main section is upon the effect of structure, and includes chapters on the chief types of compounds (principally organic), electric moments and theories of valence, electronic and atomic polarisation, and molecular association. It is evident that much still remains to be done, both in the extension of measurements and in their interpretation, but Prof. Smyth has shown himself sufficiently master of the subject not to minimise difficulties. It would not be surprising if a number of these were found to be connected with quantum resonance, or were resolved in some similar manner in the theory of molecules now coming from Hund, Slater and others. The last section consists of tables of molecular moments.

Debye and Errera have left Prof. Smyth with the least interesting part of the work ; he is to be congratulated on having made it readable as well as useful.

A Textbook of Thermodynamics. By F. E. Hoare. Pp. xii+271. (London : Edward Arnold and Co., 1931.) 15*s.* net.

MR. HOARE has been successful in writing a treatise on thermodynamics which gives a very clear account of the theoretical side of the subject and an unusually detailed description of its applications. The reviewer has had an opportunity of testing some parts of the book in a recent course on thermodynamics of an introductory character and has found the descriptions both accurate and lucid. The author, who holds the diploma of the Imperial College, has evidently been influenced by the teaching of the late Prof. Callendar, and excellent use is made of the latter's work on the properties of steam. Experimental results are frequently quoted, and some numerical examples are included in the text. For the benefit of the student who finds difficulty in applying thermodynamic principles in practical cases, we should like to see numerical exercises added in a second edition. The work can be recommended to students who are taking an honours degree in physics.

We note that Mr. Hoare does not adopt the terms 'enthalpy' or 'free energy'. It may be suggested that the time has come when some decision should be sought by international agreement as to the nomenclature and notation to be used in the practical and theoretical aspects of the subject of heat. H. S. A.

The Nature of a Gas. By Prof. Leonard B. Loeb. Pp. x+153. (New York : John Wiley and Sons, Inc. ; London : Chapman and Hall, Ltd., 1931.) 12*s.* 6*d.* net.

THIS monograph is published under the auspices of the National Research Council of America and is the first of a series related to electrical insulation. Gases are utilised as insulators and also occur in insulating materials, and knowledge of their properties is of importance to those responsible for the design and construction of electrical apparatus of all descriptions. The book contains three chapters, the first an introduction describing modern theories of the electrical constitution of atoms and molecules, the second giving an account of the kinetic picture of a gas, and the third dealing with ionisation phenomena.

The first two chapters are concerned mainly with researches already familiar to the physicist, and many readers will turn with special interest to the third chapter in which Prof. Loeb's own work rightly finds a place. Much useful information is here incorporated, but we must confess to some measure of disappointment with the result. This is due in a large measure to the many problems still unsolved in this branch of physics, but in part to the use of terms, such as 'elastic' and 'inelastic' collisions, which are not adequately defined. As the author points out, too much of the 'how' of the processes described can scarcely be looked for, and we must content ourselves at present with the bare facts.

Vector Analysis : with Applications to Physics. By Prof. Richard Gans. Authorised translation from the sixth German edition by Winifred M. Deans. Pp. ix+163. (London, Glasgow and Bombay : Blackie and Son, Ltd., 1932.) 12*s.* 6*d.* net.

THE special features of this book are the emphasis laid upon the applications of the subject and the forty-four examples with their full solutions (occupying fourteen pages) in an appendix. The first chapter deals with scalar and vector products and their applications, chiefly to electric circuits. The second introduces differential operations ; after defining gradient, divergence and curl we are given many applications to mechanics and physics. An interesting historical note points out that the symbol like an inverted delta was first introduced by Hamilton, who called it "nabla", after a Hebrew stringed instrument. The third chapter deals with orthogonal curvilinear co-ordinates, with applications to Laplace's equation, wave motion, and rigid dynamics. The fourth chapter, headed "Tensors", is disappointing. It opens well by following the historical development of the subject, which is connected with elasticity, but it is misleading to state that "A tensor is determined by six numbers", and the whole of the chapter seems spoilt by the implicit assumption that all tensors are necessarily of the second order and in three dimensions. The fifth and last chapter deals with applications to hydrodynamics and electrodynamics. Except for the tensor chapter, the book appears likely to be useful to students of applied mathematics and physics.

Leçons sur la géométrie projective complexe. Par Prof. E. Cartan. D'Après des notes recueillies et rédigées par F. Marty. (Cahiers scientifiques, Fascicule 10.) Pp. vii+325. (Paris: Gauthier-Villars et Cie, 1931.) 80 francs.

IMAGINARY elements in geometry were for a long time considered solely as an auxiliary to the study of real points. Projective complex geometry, considered as an independent branch of mathematics, owes its origin to von Staudt (1858) who introduced the notion of a chain, and it was greatly developed by Juel (1885) and Segre (1889). The latter showed the importance of *antiprojective* transformations, *anti-involutions* and *antipolarities*. Prof. Cartan treats complex projective geometry from a higher point of view, linking it with non-Euclidean geometry of three dimensions, following the example of Poincaré, who linked real projective geometry with non-Euclidean geometry of the plane.

The first part of the book is restricted to the projective geometry of the complex line and its relations with the geometry of Lobatchewsky. The second part deals with the complex projective geometry of three dimensions. The last chapter treats of the harmonic polynomials of complex projective space and their applications to the representation of this space, or rather of Hermitian elliptic space, by real algebraic varieties without singularities contained in a Euclidean space of a suitable number of dimensions. The writing is clear and attractive, and the book is a useful exposition of one of the less-known branches of geometry. H. T. H. P.

Miscellany

This World First. By J. H. Curle. Pp. v + 212. (London: Methuen and Co. Ltd., 1932.) 6*s.* net.

MR. CURLE is like the road-mender who, when accused of pessimism, said "I ain't no pessimist; I thinks badly o' most things and most people—that's all." Mr. Curle declares himself to be no pessimist; but he sees the world as a series of problems or riddles. Thus: Nature, on one hand a thing of beauty and perfection, on the other is "a spectacle of overwhelming cruelty and horror", which makes "the idea of a Living, Personal God" behind it "a nightmare" and unthinkable; Christianity is dying after nearly two thousand years; Western civilisation is nearly at an end; and science "deeply enheartening when we think of genetics, psychology, bio-chemistry, and medicine; deeply disconcerting when we think of aspects of relativity, of physics, of bacteriology, of poison gas, of weapons of war". We need pursue the list no further. The problems are such as present themselves to all who are not content with a blind acceptance of things as they are, and a familiar symptom of the questioning spirit, which for our good, if not for our comfort, has been all pervasive since the War.

Mr. Curle has travelled widely and pondered his many and varied experiences. As the result he sees a way of escape from pessimism on the line he has suggested in the title of his book: "This World First". If we may no longer look for the intervention of a personal God in the arena of the struggle between good and evil, which we call the world, man must take up the cudgels on his own behalf. Holding fast to the beauty of the world, he must co-operate with law and order in Nature against cruelty and oppression; he must fight on the side of science for the betterment of mankind in the war against degeneracy and disease. Mr. Curle thus sees the solution of his problems in the form of a duty of us all to make secure and hold the good against the encroachment of evil. If this does not help us "to grasp the sorry scheme of things entire", it is at least a sound enough practical philosophy for a work-a-day world which is content to leave the riddle of the universe to solve itself while it "gets on with the job".

Astronomische Paradoxa. Von Dr. Georg Alter. Pp. 72. (Prag: J. G. Calve'schen Universitäts-Buchhandlung, 1932.) 25 Kč.

THIS work is a series of short essays explaining a number of points that often cause perplexity to students of astronomy. The earlier ones are elementary; why the sun is not on the meridian at 12 o'clock; why the moon's orbit is concave to the sun, though it revolves round the earth; why it is winter when the earth is nearest to the sun. The following ones are more difficult; why the crest of the tidal wave lags behind the moon; the effect of the earth's rotation on the motion of projectiles, etc.

Chap. viii explains why the effect of a resisting medium is to shorten the time of revolution, although it reduces the initial speed of the body. Chap. ix deals with the Einstein bending of light by the sun, and explains why the star's image is pushed outwards though the light rays are bent inwards. The final chapter explains why the variation oval of the moon is pushed inwards at full and new moon, though these are the points where the outward perturbing forces are strongest; this is a cause of perplexity to many. The author's explanation would not be clear to the 'man in the street', as it needs a considerable knowledge of dynamics.

Some of the problems dealt with are explained in nearly all astronomical primers; but the explanations in this book are fuller and more rigorous than those often given. The mere fact of a result seeming bizarre and unexpected often attracts the attention of earnest students.

Fractures. By Meurice Sinclair. (Modern Surgical Monographs.) Pp. xxxiv + 550. (London: Constable and Co. Ltd., 1931.) 24*s.* net.

THE exceptionally vast and various experience of the treatment of fractured bones provided by the War was responsible for bringing this, like many other departments of applied science, to a

high pitch of efficiency. The author of the treatise under notice, who gives a comprehensive and lucid account of what was learned during those years of strict discipline, complains that in spite of the ever-increasing incidence of traffic and road accidents, there is a widespread tendency to relax the thoroughness of remedial measures, which the War taught surgeons to regard as vital and essential in this department of treatment, so vastly important not only from an æsthetic point of view but also even more so for its economic and utilitarian bearings.

Hence Mr. Sinclair has written this excellent book as an appeal for increased efficiency and care in treating fractures and as a guide for surgeons to the methods that are essential for attaining the best results in practice. It is illustrated with 337 X-ray photographs and diagrams and should become the means of instructing every medical student how to deal with fractured bones.

An Egyptian Axe Head of Great Antiquity

IN NATURE of April 18, 1931, I described the investigation of an Egyptian axe head of date 1800 B.C., supplied to me by Mr. Guy Brunton, and showed how it was possible to reproduce it by the ordinary laboratory methods of to-day. Recently, at his request, I have examined an axe head which is many years older. It was found by Mr. Brunton last winter during his excavations at El Matmar south of Assiut in middle Egypt. He informs me that it can be well dated to what is known as the middle Pre-Dynastic period and early in that; that is, roughly about 4000 B.C. He adds: "I know of no other copper implements anything like as early as this with the exception of small pins and such-like; consequently it has a very considerable importance."

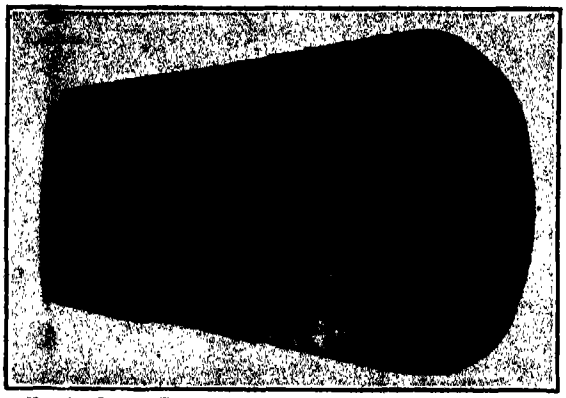

FIG. 1. Middle Pre-Dynastic axe head from Middle Egypt. Reduced by 3/5.

The axe weighed 3 lb. 7 oz. One side of it, reduced by three-fifths, is shown in Fig. 1. It was coated with a thick patina of malachite and azurite with some patches of sandy material adhering to it. Part of one side of the axe was ground and polished; the area so treated is outlined in the top right-hand corner of Fig. 6. Under the coating of carbonate was a layer of cuprite, beneath which was the original copper-coloured metal, apparently sound. When the exposed metal had been polished and examined with the microscope it was found to be differentially corroded, the corrosion product (cuprite) forming a dendritic structure which suggested at once that the metal was a cast alloy with a 'cored' structure. This was confirmed by etching the surface with ammonia and hydrogen peroxide. The structure developed in this way is shown in Fig. 2 at 100 diameters, in which the black corrosion product is seen to coincide with the dark 'cores'.

To reveal the structure of the metal more clearly, the surface was ground to the depth of about one-tenth of an inch, which was sufficient to remove the superficial layer of partly corroded metal. The microstructure of the metal at a point corresponding to *A* in Fig. 6, is shown in Fig. 3 at a magnification of 100 diameters. As is mentioned above, its 'cored' structure indicates that it is a casting of high copper content. Superimposed on the 'coring', however, is a granular twinned structure which shows that the alloy has recrystallised under the influence of strain and heat. This structure could be produced either by hammering the casting cold and then annealing it at a moderately high temperature—the persistence of the coring indicates that the annealing temperature

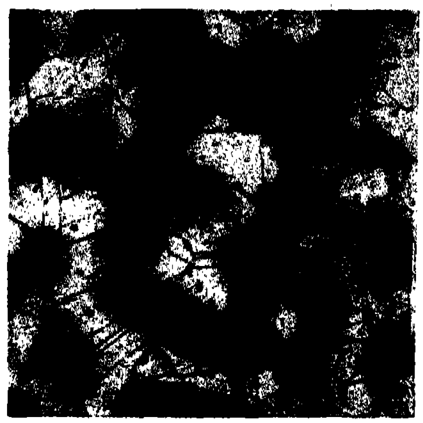

FIG. 2. Microstructure of metal beneath corrosion products. ×100.

could not have been above, say, 800° C., or by hammering the metal hot. Some of the grains in this micrograph contain striations which show that the axe has been cold worked after the recrystallisation occurred. The effect of this mechanical treatment is shown more clearly at a magnification of 200 diameters in Fig. 4 which reveals, in addition to the strain markings, considerable distortion of the twin bands. Near the cutting edge of the axe, the distortion of the metal was much more pronounced

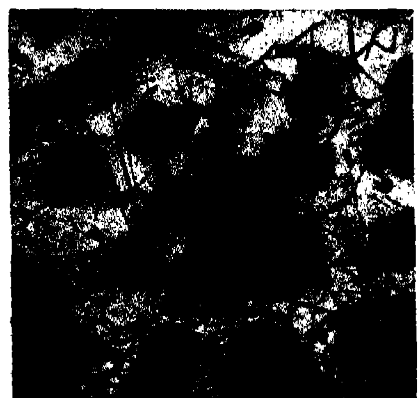

FIG. 3. Microstructure below superficial layer. ×100.

than elsewhere, as is shown by a comparison of Fig. 5 at 100 diameters, which represents the structure at point *B* in Fig. 6, with Fig. 3. This indicates that the axe had been more heavily worked at the edge and suggests that the purpose of the final cold working was to harden the metal.

Drillings for analysis were taken from one of the side edges of the axe head. The main constituents found and their percentages were as follows: copper, 97·35 per cent, nickel 1·28 per cent and

arsenic 0·49 per cent. Metals present in smaller quantities were, lead 0·17 per cent, iron 0·15 per cent and manganese 0·06 per cent. In addition traces of tin and antimony were detected. There remains about 0·5 per cent to account for. This consisted almost entirely of the oxygen present in the corroded products, of which cuprite was the principal. The fact that tin is present only in traces need cause no surprise and is, indeed, to be expected from the great age of the axe head, for as Sebelien

FIG. 4. Microstructure below superficial layer. ×200.

has shown, the Egyptians had not learned how to make bronze until the later dynasties. It is unlikely that any of the elements present in the copper were added intentionally for the purpose of hardening the metal. Almost certainly they were derived from the ores from which the copper was smelted.

Brinell hardness measurements were made at various points on the polished surface of the axe using a 1 mm. ball. The results, which are shown in Fig. 6, were rather irregular, varying from 63 to

FIG. 5. Microstructure at axe edge. ×100.

73 on the flat and increasing considerably near the cutting edge to a maximum figure of 85. The Brinell hardness of an alloy of this composition in the cast or annealed state would be about 50, so it is clear that the axe has been work hardened, no doubt by cold hammering. All the data lead to the conclusion that it was cast roughly to shape and then either cold-hammered and annealed or hammered when hot. After this treatment, which was perhaps a shaping operation, the axe was hardened by hammering it cold, most severely near the edge. In spite of its great antiquity—it is nearly six thousand years old—this axe head has retained a considerable amount of the hardening artificially conferred by work. In this respect it confirms the results of my previous investigation of an axe head about 3,700 years old. The maximum hardness figure is lower, namely, 85, as compared with 112, but the alloys have different compositions and the older axe head is probably rather softer in the annealed state. The Brinell hardness would probably be about 50 as compared with 54. The retention of cold work in alloys of this type may thus be regarded as sufficiently established. Accepting Mr. Brunton's date, it is clear that six thousand years ago, the Egyptians were casting, heat-treating and cold-working copper alloys of these types.

I acknowledge with pleasure the assistance of

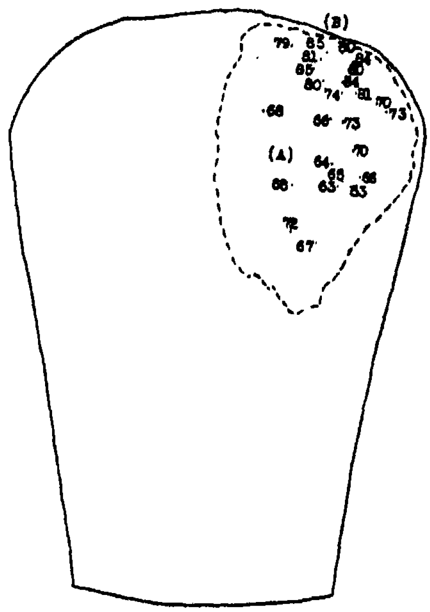

FIG. 6. Outline of axe head and Brinell hardness numbers. The scale of the diagram is one half.

two members of my staff, Mr. C. W. Dannatt and Dr. M. S. Fisher, in the above investigation.

Possible Existence of Multiply Charged Particles of Mass One

THEORETICAL arguments justify the assumption that, while nuclear electrons elude every dynamical treatment, the dynamics of the particles of proton mass in the nuclei is in accord with the general quantum-kinematical scheme.[1] The forces of interaction, however, seem to exceed ordinary Coulomb forces considerably. The binding energy E per particle, for example of a system of two particles of proton mass M in its lowest quantum state, should be for attractive Coulomb forces between the particles:

$$E \sim \frac{Me^4}{8h^2} \sim 6000 \text{ electron volts,}$$

that is, about a thousand times less than the actually

observed binding energy per proton in the α-particle.

On the other hand, the remarkable phenomenon of the anomalous scattering of hard γ-rays cannot be ascribed either to nuclear electrons, because it is known from experimental results concerning the statistical properties of nuclei, that the electrons do not exist in the nucleus as dynamical units, or to proton dipoles, because it is known that the application of the ordinary formula for the scattering coefficient σ:

$$\sigma \sim \frac{8\pi}{3}\left[\frac{e^2}{Mc^2}\;\frac{\nu^2}{\nu_0^2-\nu^2}\right]^2$$

(where ν, ν_0 are the frequencies of the scattered light and of the proton oscillator) leads to intensities of the scattered radiation which are about a thousand times smaller than the observed ones.[3] It should be noted, that in both these cases, where we observe gross and roughly equal departure from simple theoretical formulæ, the formulæ contain the charge in the fourth power.

We know that the constancy of the charge of the particles of mass one is not unlimited: transitions from charge e to zero must occur (proton and neutron). The neutron must not be considered as a diminutive hydrogen atom, but as an elementary particle just like the proton, because of its statistical properties.

Applying this view to the above-mentioned experimental fact, I suggest the following generalising hypothetical assumption: *the particle of mass 1 may have arbitrary, positive and negative (but perhaps only integral) values of its charge.* The stability of a given charge value against β-decay or against its reverse process depends on the quantum state of the particle. In particular it is assumed that a free particle is stable with charge e or zero, an α-particle is stable with charges of about $+6e$ and $-5e$ (in order to explain discrepancies of the order of 1000 in quantities depending on e^4.)

This explains both the strong forces which prevail in the nucleus, and the strong anomalous scattering of hard γ-rays. Virtual forces due to exchange of charge or similar ones can be dispensed with.

The question arises, whether particles in a state of higher charge, if suddenly set free by hard collisions, are sufficiently stable to be observed. With all necessary reserve (because of the uncertainty of the experimental data) I suggest that two phenomena may be interpreted on these grounds:

1. Hoffmann, Steinke and Schindler have observed the production by cosmic rays of secondary particles of high ionising power and kinetic energies certainly greater than 10^8 volts, that is, energies which are great compared with the binding energies of the elementary particles in the nucleus. They suggest that these particles should be complex nuclear fragments. It is, however, necessary to consider, that the nuclear binding forces are negligible compared with the forces which effect such enormous transfers of kinetic energy. In that case only elementary particles can be ejected. I suggest that in these cases particles of mass 1 and of high charge are set free and take some time before arriving at their stable charge value (e or zero). The majority of the rays reported by Steinke and Schindler (those giving 3×10^6 ion pairs) can be ascribed to particles of mass 1 and charge between $5e$ and $6e$.[2]

2. The outstanding difficulty in the interpretation of the experiments on cosmic rays is the fact, that the particles, the distribution of which is only slightly affected by the earth's magnetic field, seem to be absorbed largely in the earth's atmosphere. (The ionisation at 28 km. height is about sixty times bigger than at sea level; in particular, there appears to be absorption already in the first two metres of water-equivalent.) I suggest that the decrease in ionisation in passing downwards from the upper layer of the atmosphere may be due not to a decrease in the number of ionising particles but to a decrease in ionising power, and this in turn to a decrease in the charge. The particles of mass 1 and high *positive* charge may in the interstellar space find no chance to collect electrons for compensating their charge and enter the earth atmosphere in the state into which they were originally dissociated. This assumption could easily be tested by measuring the *number* of particles up to great heights and comparing the results with the variation of *ionisation*. Only the latter has been measured so far.

Atmospheric Conditions and the Kennelly-Heaviside Layer

SINCE 1925, I have made observations upon the signal strength of KDKA in Pittsburg. The observing station at Morgantown, West Virginia, is sixty miles due south of KDKA. My results are in complete agreement with the discoveries of Prof. Ivo Ranzi[1], provided I assume that the 309-metre wave from KDKA behaves like a 100-metre wave in so far as the E layer is concerned.

The following quotations from my published articles should be compared with the statements of Prof. Ranzi: "The night signal may be equal to, greater than or less than the day signal. A rising curve (stronger signal) after nightfall indicates cloudy or stormy weather, while a falling curve (weak signal) is likely to be followed by clearing weather".[2] "Weather conditions have a decided effect upon the signals from KDKA. So much so that it is even possible to foretell the weather one day ahead by the form of the fading curve".[3] "When a high pressure area covers both Pittsburgh and Morgantown, the day signal from KDKA is stronger than the night signal; while for a low pressure area, the night signal is stronger. If the storm centre passes to the south of the observing station, the fading curve from a station to the north is no longer reliable."[4]

Apparently these variations depend upon the changes in the E layer. During the day the received signal is made up of two parts: the ground wave and a weak sky wave reflected from the E stratum of the Kennelly-Heaviside layer. If there is a low pressure area to the north of Morgantown, the sky wave increases at night and so the night intensity is greater than that by day; if, on the other hand, a high pressure area lies to the north, the E layer disappears rapidly after nightfall and the night signal drops below the day signal. The changing intensity acts like a barometer in indicating the presence of cyclonic and anticyclonic conditions and so has considerable value in weather forecasting.

With this method of fading curves, our weather

prognostications were about ninety per cent correct for the periods in 1927, 1928, 1929 and 1930 during which it was used. The results in February and March of each year averaged only eighty-five per cent. These observations have been discontinued temporarily on account of a prolonged drouth in this section of the United States.

Post Office Reform

ALL who realise the weaknesses of the present system of 'secretariat' control as practised in the great departments of State will endorse the view expressed in the leading article on Post Office reform in NATURE of October 15, p. 557, where it is stated that the Bridgeman Committee has rendered an important public service by the emphasis it places upon the need for bringing the engineers in the Post Office more effectively into the consideration of matters of policy. As is rightly pointed out, the principles of organisation which the Bridgeman Committee recommends should be applied to the Post Office, call for a wider application; and, for the reasons indicated below, the most valuable result of the Committee's recommendations may ultimately prove to be not so much in the reform of the Post Office as in the reactions on the whole structure of administrative control in the public departments.

There is a feeling in some quarters that the Committee's recommendations, if carried out, will dispose of all legitimate complaints on the part of the technical men in the Post Office. The Engineer-in-Chief (and other heads of departments) would, for the first time, be brought into discussions on matters of policy, as of right and in open council; and the possession of technical knowledge and experience would no longer, in practice, debar the engineers from advancement to purely administrative posts. Actually, however, as is hinted in the article in NATURE, acute controversy is certain to arise on the application in the provinces of the Committee's recommendations. It is indeed not unlikely that the position of the now autonomous engineering staff outside headquarters may be positively worsened if the Report is put into effect as it stands; for it is an integral part of the Committee's proposals that executive responsibility should be taken away from the Secretariat and placed upon 'regional directors'. Post Office and Civil Service tradition being what it is, these posts will naturally fall, in the main, to the senior members of the Post Office staff in the provinces, namely, the so-called 'surveyors', whose vestigial title is of itself sufficient evidence of the course of Post Office evolution as an essentially mail-carrying organisation. By its rejection of the almost time-honoured proposal for separating the administration of the telephones from that of the mails, and by its specific recommendation that the post of 'surveyor' should be re-labelled 'regional director', the Committee has rendered it an almost foregone conclusion that the regional directors will be the surveyors 'writ large'.

It must be remembered that the surveyors as a class have taken little or no part in local telephone administration, which has in practice been left to the superintending engineers and the district managers. The result of applying the Committee's policy of a unified administration for all Post Office services would appear to be, inevitably, that, for perhaps a generation, the provincial control of the telephone service will pass into the hands of those who, however gifted in the administration of the mails, were described by the Select Committee on Telephones of 1922 as "a fifth wheel to the coach" in regard to telephone administration. In short, what the Post Office engineers may gain at headquarters and in occasional admission to the sacred preserves of the Secretariat is likely to be lost in the provinces by their submergence, in company with other telephone staff, in an organisation nurtured in the mails tradition.

For the Bridgeman Committee's reforms to have their full effect in promoting administrative elasticity and rapid development in the telephone service, it would seem to be essential for the telephones to be separated from the mails in accordance with the views expressed by (among others) the Select Committee on the Telephones of 1922, the Chambers of Commerce, and the engineers themselves in the evidence submitted to the Bridgeman Committee through the Institution of Professional Civil Servants. Such a separation, under whatever form of public control, would result in the administration of the telephones by telephone men, technical and non-technical. The Committee, while agreeing that theoretically separation would be the ideal solution, recommends against the proposal in view of the manner in which the mails, telegraphs, and telephones have become interwoven in Post Office administration. It cannot be denied that the difficulties of segregation during the transitional period would be considerable; but, on the other hand, it cannot be questioned that the ultimate advantages accruing from such a policy would be so great that it would be well worth while to face any temporary difficulties that might arise.

Absence of Mitosis in Tissue Culture and Regeneration in *Helix aspersa*

IN recent work on regeneration in the mantle cavity wall of *Helix aspersa* and on the metamorphoses of pieces of the wall kept in blood,[1] no mitosis has been found. Such cell divisions as occur are amitotic. These can be watched *in vitro*, in the hanging drop preparations.

In *Janella*, L. Plate[2] describes the regeneration of cells lining the breathing tubes as occurring exclusively by amitosis.

Normal mitosis takes place, of course, in the hermaphrodite gland, but so far as I know, in the half-grown and adult snail, amitosis is the only method of cell division in somatic tissues I have examined. Possibly some of the readers of NATURE have a series of *Helix* embryos, and it would be interesting to know whether they can find normal mitosis in the somatic tissues, and up to what age.

Occurrence of a Paired Parietal Bone in a Snake

A GENERAL conception of zoologists is that the parietal bones are always fused into a large unpaired bone in Ophidia. During our recent investigation of the skeletal systems of different reptiles we found from an alizarine preparation of transparency that

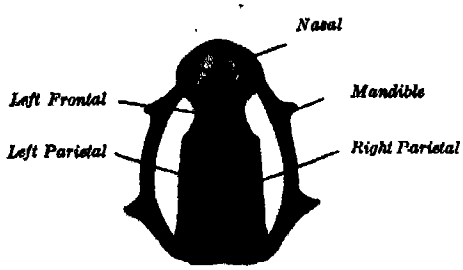

FIG. 1. Dorsal view of the skull of *Typhlops braminus* showing the paired parietal.

Typhlops braminus has a distinct paired parietal bone (Fig. 1). Perhaps their occurrence as such escaped the notice of the former investigators, the size of the skull being very small and alizarine preparation of transparency being unknown to them. The details of the skeletal system will be published elsewhere.

Prof. P. E. Richards and NATURE

THE letters of the late Prof. Philip Ernest Richards (died June 4, 1920) recently published under the title "Indian Dust" (Allen and Unwin) contain a most interesting reference to the jubilee number of NATURE. Richards was appointed in 1911 professor of English literature to the Dyal Singh College at Lahore, transferring in 1914 to Islamia College in the same town. The letter in question is dated Jan. 23, 1920, and is addressed to his mother:

"The jubilee number of NATURE has fallen into my hands. It presents a portrait of Norman Lockyer, the founder and editor. Here is the man who found something in the sun before it had been found on the earth. Surely a wonderful fellow—far more wonderful than he looks. But I think he looks wonderful. Many articles in the paper review the progress of science in many different branches during the last fifty years. I do not understand one eighth of any article, but I have read them all, and derived a deep sense of satisfaction—joy, I might say. Here are men who have something to live for, and who have much to show for what they have been doing. They are the best sort of men in the world, and the world ought to belong to them, and not to Prussians and Bolsheviks or Indian extremists. But poor humanity is far behind its leaders. Nevertheless, the world is worth living in for the sake of Science—and Literature—and all the other Arts."

Radiographs of Insects

IN a letter to NATURE of Sept. 17, 1932, Dr. Hugo Fricke and Irwin Sizer state, in an account of their own radiographs of insects, that they could not find previous records of such radiographs. We made and published such radiographs five years ago[1,2,3], chiefly with *Deilephila euphorbiæ* pupæ, when carrying out research work on metabolism during metamorphosis of insects. Particulars of the methods used, the results, and about seventy radiographs, can be found in the papers referred to below.

The radiographic method was afterwards found useful in economic entomology, and we have made radiographs of insects for the Department of Sylviculture. The distribution of parasitic hosts in populations of hundreds of pupæ can be shown in one single radiograph without injury, and further development can be observed by the same method.

Colonisation of the Sea by Insects

THE letter from Dr. Hem Singh Pruthi on this subject[1] is of much interest, but one feels doubtful whether the comparative absence of insects from the oceans can be accounted for simply on the ground of calcium deficiency. Even supposing that the remarkable instance of the *Clœon* larva, which he cites, is to be connected with the unusually high concentration of calcium in the waters of the Salt Range, there remains the fact that many species of Coleoptera (Dytiscidæ, Hydrophilidæ), as well as Hemiptera (Corixidæ) and Diptera, have been recorded from waters of a salinity equal to or greater than that of the sea, but in which the proportion of calcium was no higher.

Several species of insects which I myself have recorded[2,3] from saline waters, both on the south coast of England and in the desert regions of California, are listed in the accompanying table.

Insect.	Range of Specific Gravity to which exposed.	Locality.
Hemiptera		
Corixa selecta .	1·009–1·035	Sussex, England
Coleoptera		
Octhebius marinus	1·014–1·035	Sussex, England
Octhebius rectus	1·024	Death Valley, California
Philhydrus maritimus	1·009–1·035	Sussex, England
Diptera		
Culicoides nubeculosus	1·022 (circa)	Somerset, England
Ephydra hians	1·024	Death Valley, California
Ephydra riparia	1·026–1·035	Sussex, England
Nemotelus uliginosus	1·000 (?)–1·035	Sussex, England

In each case, although the specific gravity of the water to which the insects were exposed was almost

as great if not greater than that of the sea, analysis showed the proportion of calcium to be definitely lower. In the case of the Californian locality, the amounts of calcium and sodium were 84 and 9010 parts per million respectively, whereas in sea water the amounts in parts per million are approximately 420 and 10,700 for calcium and sodium respectively. Therefore the inability of these and allied forms to colonise the sea itself can scarcely be explained on grounds of calcium deficiency.

Secondly, the Caspian Sea may be cited as an example of a type of lake which, while of a lower total salinity than the ocean, has a much higher proportion of calcium and magnesium salts. Yet insects do not appear to have been strikingly more successful in adapting themselves to saline conditions here than elsewhere.

Susceptibility of English *Culex pipiens* L. to Infection with Bird Malaria

In a recent letter[1] we described a method of inducing females of *Culex pipiens* to gorge on canaries. We have utilised this method for experiments on the infection and transmission of bird malaria by English *C. pipiens*. In the course of our experiments 393 mosquitoes gorged on birds heavily infected with malaria (*Plasmodium relictum*, Grassi and Feletti). 131 of the mosquitoes were dissected and 72 (55 per cent) were found to be infected. On dissection many of the mosquitoes showed more than twenty cysts on the stomach and the salivary glands were heavily infected with sporozoites. The infected mosquitoes readily transmitted the malaria parasite to healthy canaries.

So far as we know, there is no published record of the transmission of bird malaria by *Culex pipiens* in England. It is interesting that, once the experimental difficulties of breeding and feeding the English *Culex pipiens* are overcome, it behaves as a normal vector of bird malaria.

The Vitamin Factor in Dental Caries

Is there not a possibility that the vitamin factor in the production of dental caries is unduly emphasised? That malnutrition may precipitate and intensify decay of the teeth is beyond question, but exception may surely be taken to the inference that if the proper vitamins are present in food all will be well with the teeth. Australian experience is strongly against such an assumption. Here the incidence of caries is admittedly high, but Australia is a land flowing with milk and vitamins; cows are exposed to sunlight throughout the year, whilst fruit and vegetables are abundant, of good quality and cheap.

A distinguished English biochemist, to whom I referred the argument, suggested that the low phosphate content of Australian soils might be the causative factor, but this is easily ruled out, for deficiency in phosphate lowers the yield of food stuff per acre rather than the phosphate content of such food. Anyhow, if low phosphate were its cause one would find this reflected in the growth of bone; and yet twenty-eight years' association with Australian youth has continually aroused in me a deep admiration for his magnificent physique. Are we not dealing with one of those biological degenerations which may overtake any organ and will lead to extinction of such unless selection is kept busy?

Formerly the edentulous human suffered from grave malnutrition, and the girl with pronounced caries was not only physically unattractive but also repellent. The modern excellence of the dentist's art has stopped both forms of selection and so may we not expect human teeth to go the way of the snake's legs?

Further Doublets of As V

While examining the spectra obtained by passing varying discharges through the vapour of pure metallic arsenic contained in capillary tubes, certain lines were found to be even more strongly enhanced than those due to the trebly-ionised atom, with increase in the intensity of excitation. A strong doublet at λλ 2902, 2785 which was completely suppressed by the introduction of the slightest inductance in the circuit was therefore ascribed to the quadruply-ionised atom of arsenic.

Sawyer and Humphreys[1] reported the identification of four pairs forming the first members of the doublet series of As V. The above pair is found to be the combination $5s\ ^2S_1 - 5p\ ^2P_{1,2}$ and is in perfect agreement with the corresponding pairs in the sequence Cu I, Zn II, Ga III, and Ge IV. The value of the term $5s\ ^2S_1$ found by Sawyer and Humphreys ($\nu = 241540$ cm.$^{-1}$) led to the values $\nu = 207096$ and 205648 cm.$^{-1}$ for the $5p\ ^2P_1$ and the $5p\ ^2P_2$ respectively with the difference $5p\ ^2P_1 - 5p\ ^2P_2 = 1448$ cm.$^{-1}$ This identification is further supported by the detection, in exactly the calculated position, of the inverted group $4d\ ^2D - 5p\ ^2P$.

Classification	λ (Int.)	ν (vac.)	δν	ν (calc.)
$5s^2S_1 - 5p^2P_2$	2785·35 (10)	35891·6	1447·2	
$5s^2S_1 - 5p^2P_1$	2902·38 (8)	34444·4		
$4d^2D_2 - 5p^2P_1$	1635·45 (6)	61145		61148
$4d^2D_2 - 5p^2P_2$	1609·16 (6)	62144	1448	62146
$4d^2D_3 - 5p^2P_2$	1597·61 (5)	62593	449	62591

The occurrence of these pairs of As V in a simple discharge tube leads one to think, that, as a method of excitation of spectra, this simple source affords a very wide range of ionisation of the atom, for example, As I to As V.

Buffalo Sacrifice.—The sacrifice of a buffalo at an annual festival in honour of one of the two chief village deities of Manakaddu, Salem City, Madras Presidency, is described by Mr. F. J. Richards in the *Indian Antiquary* for August. The festival is held in February or March in each year and usually lasts for some weeks. The sacrifice here described took place on March 7–8, the seventeenth day of the festival, which had begun on February 19. In the evening the processional images of the two deities, Mâri-amman and Selli-amman, are brought to the temple of Kâli, with whom Selli-amman is identified, and after the sacrifice of a sheep the images of the goddesses are carried in procession around the village, Selli-amman's vehicle being a lion and that of Mâri a horse. In front walks the pariah whose privilege it is to slay the buffalo, carrying the sacrificial knife on his shoulder. His torch-bearer is also a pariah, whose office is hereditary. The goddesses are then carried clockwise around the temple. A plaintive hymn is sung while two men rock the images of each goddess. After the singing of the hymn all females must go home. The buffalo victim is then led to the edge of a pit 50 yards in front of the temple. It must be male. After offerings have been made to the victim by the priest and it has been garlanded and sprinkled with red-ochre, sandal and saffron on the forehead, the pariah awaits the signal that the goddess accepts the victim. This is signified by the shivering of the beast. The victim is held by the people and the pariah severs the neck with two or three blows. The attendant then mixes the blood with boiled rice, which he hands to the executioner, who conveys it to his mouth and then rushes like a madman around the village, at each corner throwing a few grains of blood-sodden rice into the air. The pariahs at the graveside throw the body into the pit, and it must be completely buried before the pariah returns from his circuit of the village. The pariah returns in front of the temple and after a few ecstatic screams, the spirit of the goddess leaves him. The festival closes with the sacrifice of sheep and a general feast on the 8th or 16th day after.

Puebloan Decorative Designs.—The Elden Pueblo, 6½ miles from Flagstaff, Arizona, when excavated by Dr. Walter J. Fewkes in 1926, yielded a variety of pottery, of which the decorative designs have been studied by Dr. Walter Hough (*Smithsonian Misc. Collect.* vol. 87, art. 7). Elden Pueblo is classed as a gray-ware site dating from the 'Great Period' of Kidder and is one of the many of northern type settlements penetrating the Little Colorado area. Band designs and parallel striping are applied in agreement with the structure of the ware, that is, on the corded junctions. Bands did not disappear with the coming of the quadrant art, which is also old and was introduced from the north. Allied to the band are all-over designs made up of a network of interlocking stripes. The quadrant designs seem to mark a profound change in Pueblo cosmogony, which probably began at Elden in Pueblo III. The Elden red-ware takes on the variety of paste and design of the polychrome area of the Little Colorado valley. The whole decorative field of the Elden pottery is elaborated from the bird motive. In its early form it is not realistic, but two engaged spirals generally arising each from a triangular or wedge-shaped base are taken to be the body of the bird. No other symbol is so wide spread in time and space as that derived from the bird. At Elden it occurs in various stages of convention. As a rule two birds are represented in apposition. The most ancient form is curvilinear, expressing motion. The body is sometimes shown as a triangle, sometimes supplied with a head and a tail. The list of small units is not long. Hachuring passed out of use with the discontinuance of gray-ware, about A.D. 1250.

Mammals of Central and South-eastern Asia.—The Kelley-Roosevelt Asiatic Expedition of the Field Museum, Chicago, in a relatively short period in 1928-29, was able to cover a wide extent of territory in central and south-eastern Asia. This was due to the division of the expedition into three sections, each of which touched faunal areas not reached by the others, and the result was a collection of mammals of unusual size, variety and interest. Species are represented from very different regions so that in the systematic account, by Wilfred H. Osgood, which has just been published (*Field Mus. Nat. Hist., Zoo. Series*, vol. 18, No. 10, 1932), inhabitants of the tropical coast of Cochin China rub shoulders with alpines from the highlands of western Szechwan near the Tibetan border. The accounts, however, show that in spite of its temperate climate western China possesses a mammalian fauna many elements of which extend into French Indo-China. To some extent the area covered overlaps that from which the late Oldfield Thomas obtained collections, and the author pays a warm tribute to the co-operation of the scientific staff at the British Museum, in which are housed the type specimens of new forms collected by the French ornithologist, Jean Delacour, whose mammal collections also are described in the Field Museum memoir.

Innervation of the Crustacean Heart.—J. S. Alexandrowicz (*Quart. J. Micr. Sci.*, vol. 75, Pt. 2, pp. 181–249, 3 pls., 1932) gives an account of the innervation of the heart of decapod Crustacea. Three systems of nervous elements can be distinguished: (1) a local system of neurones in the heart itself; (2) nerve fibres connecting the heart with the central nervous system; (3) nerves supplying the valves of the arteries which issue from the heart. The first system consists of a nerve trunk in the dorsal wall of the heart from which branches pass to the muscle-fibres of the heart. The cells in this nerve trunk are of two kinds—large and small—and their number was found to be constant; in *Cancer pagurus*, *Maia squinado* and *Homarus vulgaris*, five large and four small cells were present, but in *Potamobius astacus* there were eight large and eight or may be nine or ten small cells. The cells are multipolar and their long processes (the axons) after sending out short branches (regarded as dendrites) give off long branches to all the muscles of the heart including those of the ostia. The fibres which connect the heart with the central nervous system arise from the subœsophageal ganglion, travel in the nerves which run on the thoracic muscles to the dorsal side of the heart, where they pierce the wall and reach the local system. The thicker fibres, possibly inhibitory, break

up into richly arborising branches forming a neuropile which is the field of conjunction of these fibres with each other and with the neurones of the local system. The nerves of the third system, forming four pairs, arise from the thoracic nerves and innervate the valves of the arteries, except the ophthalmic artery which has a separate nerve from the stomatogastric system. The local system is an autonomic nervous apparatus from which the muscles of the heart receive impulses necessary for their regular contractions; the nerves to the valves bring about contraction of the muscle fibres of the valves during the diastolic period.

Alcohol and Inheritance in Guinea-Pigs.—An extensive experimental investigation of the effects of alcohol on guinea-pigs, made by Miss F. M. Durham and Miss H. M. Woods, has been issued by the Medical Research Council as Special Report No. 168 (London: H.M. Stationery Office, 1932). Prof. Stockard found that treatment of guinea-pigs with alcohol by inhalation led to the appearance of abnormalities which were inherited, also to reduced fertility and higher mortality records. Repetition of these experiments with careful controls leads to negative results, and it is suggested that a smaller amount of green food may have caused a deficiency of vitamins and so produced some of the abnormal offspring in Stockard's experiments. In the present work four successive generations of guinea-pigs were treated with alcohol by inhalation from a half-saturated atmosphere. Ten abnormalities occurred among 6,309 alcoholic stock and one among 674 control stock. There was no evidence that fertility was affected by the alcohol, or that males were more affected than females. A certain decrease in fertility occurred, which is ascribed to genetic qualities in the stock and the effects of inbreeding, but the controls were not extensive enough to prove this point. Some deterioration in weight also occurred, but this, too, may be due to inbreeding. The general conclusion is reached that there is no evidence that alcohol has had a deleterious effect on the genetic behaviour of guinea-pigs, and this is in accord with the results of most other workers.

Management of Race-horse Paddocks.—Prof. J. A. Hanley gives an account of management of race-horse paddocks in the *Student's Gazette* of the Royal Agricultural College, Cirencester, for 1932 (vol. 19, new series, part 1). The type of grass required differs in many respects from that which the farmer wishes to obtain and the methods of management in the two cases must in consequence be different. Paddocks used for exercise, for example, should have a soft springy turf or 'mat', a condition which a farmer would regard as indicating a serious state of deterioration. Owing to the great value of race-horses, oats and bran are fed without stint, and too little attention is often paid to the value of paddocks for grazing. Further, hand feed is apt to be deficient in lime, a danger for which fresh grass is the best natural corrector. To meet the varying needs of the yearlings, breeding mares and foals, and to provide leafy herbage for grazing throughout the greater part of the year, it is evident that a number of paddocks to be used in rotation are needed, and a scheme of management, including manuring, is outlined to show how this may be done. Horses are notably selective in their grazing, so that it is essential to include some other stock (preferably polled bullocks) in the scheme if the grazing is to be of the best quality, and there seems no doubt that the performance of a horse depends in no small degree on the management of the paddocks at the stud where it was reared.

Liquid Inclusions in Minerals.—Most of the known data on the composition and concentration of primary fluid inclusions in minerals is assembled in a paper by W. H. Newhouse in *Economic Geology* for August. Sodium chloride appears to be one of the most abundant and widespread of the constituents present, especially in or adjacent to sulphide ore deposits. It is suggested that the sulphides are carried in solution with sodium chloride and probably at higher temperatures with potassium chloride. The concentration in solutions found in galena and zinc blende from the Mississippi valley ores excludes the possibility of formation by descending meteoric waters. Similar solutions were found in galena from localities where the ores are related to visible igneous rocks (Leadville, Freiberg, etc.), and it is concluded on this evidence that the only known available sources for such concentrated solutions (apart from saline deposits) are magmatic or possibly the first artesian flow from newly tapped beds containing connate waters.

The Elastic Limit of Metals.—Dr. G. Cook describes in the September *Proceedings of the Royal Society* experiments designed to test several rival hypotheses about the stresses necessary to produce elastic breakdown in a metal. The hypotheses which have been suggested include (1) definite shear stress at yielding, (2) definite total strain energy, and (3) definite energy of shear strain. The second hypothesis requires that failure may be produced by superposing a sufficiently large hydrostatic pressure on a constant shear stress which is itself insufficient to cause breakdown, and a direct test led to the rejection of the hypothesis. In the main experiments a triaxial stress, the three components of which could be varied separately, was used instead of the simplified stress systems which have usually been used in work on elastic breakdown. The triaxial stress was obtained by using a hollow steel cylinder exposed to combined axial tension and internal pressure. A large number of samples were tested and analysis of the stresses at breakdown agrees with the assumption that failure takes place when the shearing stress reaches a certain value which agrees rather closely with the limiting stress in simple torsion. A comparison of the limiting stress in simple tension experiments shows some discrepancy, and the author concludes that, while the maximum shear stress is the principal condition of failure, the mode of distribution of the stress has some influence on the yield conditions.

Intensity Distribution in a Band Spectrum.—It is a characteristic of modern spectroscopic theory that it concerns itself with the probabilities of spectral transitions and hence with intensities in spectra. Condon in 1926 gave a theory to explain the general features of the intensity distribution in band systems, but little accurate photometric work has yet been done on band spectra. R. C. Johnson and N. R. Tawde (*Proc. Roy. Soc.*, Sept.) publish a photometric study of the Swan bands of carbon (C_2 molecule). Photometric work over a large range of optical frequencies is very difficult. The method

adopted in the present work is the use of the photographic plate and microphotometer to compare the intensities at the intensity maxima of the (unresolved) bands with the intensity distribution of a calibrated tungsten lamp. The points of technique discussed in the paper are fairly well known to workers in this field. From the observed intensity distribution the transition probabilities are calculated and they agree in a general way with the Condon predictions of the most probable transitions. The experiments with different methods of excitation (bunsen flame, oxy-coal gas flame, argon discharge, and spark under glycerine) show that the populations of the different states do not agree with thermodynamic equilibrium at the temperature of the source.

Water Transport in Electrolysis.—A well-known method for determining the hydration of ions consists in adding to the solution of the electrolyte an indifferent substance such as urea, from the changes in concentration of which around the electrodes it is possible to calculate the amount of water transported by the ions. Experiments by Miss Taylor and Sawyer in 1929 showed that in the electrolysis of sodium chloride, water is transported from the anode to the cathode, the transference per faraday being greater the lower the concentration of the solution. A further investigation by Davies, Hassid and Taylor (*J. Chem. Soc.*, Sept.) extends the results, and it is shown that the transference of water increases with dilution at a rate which is too great to be accounted for by change in the transport number of the ions. It also increases with decrease in temperature, whereas the transport number of the cation decreases with fall in temperature. The calculation of the absolute hydrations of the ions on the assumption that the hydration is independent of the concentration and that the decrease in water transport with concentration depends on the change in transport number, gives impossible values of 240 and 145 molecules of water for the sodium and chlorine ions, respectively. It is concluded that, since activity considerations point to a total ionic hydration which is independent of concentration, the results obtained must be interpreted as indicating that the ions during migration transport a considerable quantity of water with which they are not chemically combined.

Astronomical Topics

Eta Aquilæ and the Cepheid Problem.—Vol. 4, No. 8 of the Publications of Michigan University Observatory contains a study of the spectrum of Eta Aquilæ by Dr. D. W. Lee. The star has been known as a variable since 1784, its period being about 7·2 days. It was soon recognised that the eclipse explanation did not fit this case and many other theories were tried in turn, the one usually accepted at present being Prof. Shapley's pulsation theory. The present paper supports this theory, but with the modification that the pulsations are to a large extent in the star's atmosphere. The spectroheliograph has enabled us to study the behaviour of gases at different heights in the sun's atmosphere, and the experience gained there may be extended to stellar spectra. D. Lee notes that if the pulsation arises from a central impulse, there would be a lag in the phases of the outer layers as compared with the inner ones; his observations confirm this, and indicate the presence of a compressional wave which is traced through four of the lower layers of the atmosphere. A companion paper by W. Carl Rufus in No. 7 of the same publication contains a diagram of the mean velocity curve for all levels. This shows a marked pause in the middle of the ascending portion of the velocity curve. The curves from hydrogen and strontium lines have a secondary maximum at this point. The light-curve has a similar pause, which is supposed to indicate a stage of comparative rest in the atmosphere.

The light maximum follows maximum compression of the body of the star by about one quarter of the period; but the maximum compression of the atmosphere would be later than that of the body, owing to the lag in the outer layers. It is concluded that the atmospheric compression plays a large part in the increase of light.

The Place of the Moon derived from Occultations.—Prof. E. W. Brown succeeded in his attempt to interest a large number of astronomers in the observation of occultations of stars by the moon. The observers are so widely scattered that the risk of bad weather is largely obviated, and a sufficient number of results is obtained every year to give a good value of the mean error of the moon in longitude. There is, however, one point that prevents us from taking the result as giving the absolute error of the moon; this is the fact that Prof. Brown rather discourages the observation of re-appearances of stars, so that practically all the observations are made between new and full moon. He gives as a reason that re-appearances are more difficult to time with accuracy than disappearances; but this difficulty can be overcome with sufficient practice; there would necessarily be fewer re-appearances observed, since the majority of them occur after midnight; this would necessitate some weighting of the results, to obtain the mean error of longitude. The present system cannot be relied on to give the true error of the moon in longitude, for errors in the assumed semidiameter and in the assumed coefficients of the variation and the parallactic inequality are not eliminated. However, the errors from these sources should be the same every year, so we can take the results with confidence as showing how the mean error of longitude is changing from year to year. Prof. Brown and Dr. Dirk Brouwer have published (*Astr. J.*, 970) their discussion of the observations of the year 1930, and also give a preliminary result for 1931. The following table gives the values for different years, with their differences:

Year.	Obs. minus Tab. Long.	Diff.
1927	+6·92″	
		−0·60″
1928	+6·32	
		−0·36
1929	+5·96	
		−0·17
1930	+5·79	
1931	+(5·6) provis.	

They conclude, from the run of the differences, that the error of longitude probably passes a minimum in 1931 or 1932, and will then increase again.

The Early History of the Cell Theory

IT is now generally recognised that Schwann was not the first to discover cells in the body of an animal but he is often regarded as the founder of the theory of the conformity in the elementary structure of plants and animals. In a recent number of the *Anatomischer Anzeiger* Prof. F. K. Studnička shows that Schwann was neither the first to make this suggestion, nor did he really prove it. He has studied the work of all the forerunners of Schwann and has attempted systematically to interpret the significance of their work.

In 1823 H. Milne Edwards came to the conclusion that the small granules ('globules') of 1/300 mm. in diameter, which he found in all the tissues he examined, are of varied origin and in great part mere artefacts. Henry Dutrochet (1824) accepted some of H. Milne Edwards's ideas (he had seen the same globules), but he made a great advance by directing attention to cells in the modern sense, as typified for example in the ganglion cells of *Helix* and *Arion* and the cells in the glands of *Helix*. In his opinion, the globules of Milne Edwards develop into small vesicles, that is, cells. He compared these animal cells not with the 'great' plant cells, but with the small 'cells', found in the walls of the latter, which probably are plastids and starch granules. According to Dutrochet, the difference between the cells of animals and those of plants lies in the fact that in plants they develop much farther than in animals and give origin to large vesicular formations, whereas in animals they retain the globular form. Dutrochet was completely mistaken in describing such 'cells' in animals, because the 'cell' (that is, the cell in plants) of those times conformed to the usual meaning of this word in English. It corresponded to what we call the cell membrane. As is well known, such cells are only exceptionally present in the tissues of animals. Rich, who has dealt with Dutrochet's work more recently (1926), takes into consideration only Dutrochet's conclusions, some of which happen to agree with our modern ideas, but he overlooks the fact that these conclusions were not sufficiently proved and were, therefore, mere speculations. Dutrochet foreshadowed the cell theory but he was not the founder of the latter.

Raspail (1827) distinguished small and large 'globules' (erythrocytes, for example) and 'cells' and pointed out that the latter may assume a very elongated form, for example, muscle, nerve.

H. Milne Edwards's observations of globules in the body of animals had some influence upon contemporary literature, but to Dutrochet's and Raspail's theories of the essential identity of the 'cells' of both plants and animals, no special attention was paid. They were regarded, not quite without justification, as unproved.

In 1835, Purkinje's pupil G. Valentin described 'granules' in the body of an embryo, 'globules' in the chorda dorsalis and 'cells' in the cartilage of the larvæ of the frog. Another pupil of Purkinje, Raschkow, described (1835) cells in the epithelium of the gums and directed attention to the similarity of the latter to the cells of plants. Following on Purkinje's description in 1825 of the vesicula germinativa in the ovum of birds and the discovery by R. Brown, in 1831, of the nucleus in plant cells, these authors also described the existence of the cell nucleus in animal cells, which had not been observed by Dutrochet and Raspail. In 1836, Johannes Müller rediscovered the cells of the chorda and cartilage.

In 1837, Purkinje communicated to a meeting of the German Men of Science and Physicians in Prague a short note on a theory of the conformity in the microscopic structures of plants and animals and directed attention to the differences between them. This was not a cell theory, and even later Purkinje firmly rejected Schwann's cell theory (1839, 1840). The great advance he made, however, was that he no longer attempted like other workers to discover the plant 'cell' in the body of animals. (We must here bear in mind that the 'cell' of Purkinje's contemporaries corresponded to the cell wall or the cell membrane in the modern sense.) Purkinje did not describe 'cells' in animals, but, more correctly, 'granules' (*Körnchen*), quite different from the 'globules' of H. Milne Edwards, and formed by a special vital substance containing a nucleus. For this vital substance, he was the first to use the term 'protoplasma' and he concluded that this substance and not the outer part, or cell membrane as we would call it to-day, formed the essential constituent of the 'granules'.

Studnička has dealt with Purkinje's work in a special paper: "Purkinjes und seiner Schüler Verdienste um die Zelltheorie"[1]. He points out that J. E. Purkinje (professor of physiology in Breslau and from 1851 in Prague) is to be looked upon as one of the founders of experimental physiology and modern histology and microscopical anatomy. He was one of the first to give an account of the methods for the study of the animal tissues and in a series of papers in conjunction with his pupils described in detail the structure of the chief tissues of the animal body. In particular Purkinje and his pupils described the 'granules' in these tissues, which represent the cells of modern histology, and so to this school (of which Valentin was a very prominent member) belongs the distinction of having been the first to recognise the manifold variety of cells in the animal body. The school of Johannes Müller also discovered the cells of the animal tissues independently, but their observations were published later than those of the Purkinje school.

Notwithstanding the advances made by the Purkinje school, Schwann (1838, 1839) in his well-known book (in which he developed his own cellular theory) returned to the views of Wolff, Oken and Dutrochet. For him, the outer part (cell membrane in the modern sense) was the essential constituent of the 'cell' and he attached no special importance to the cell contents. Nevertheless his views came to be widely accepted and quite overshadowed those of Purkinje, the consequence being that his name became associated with that of Schleiden as the joint founder of the cell theory. So far as the completely mistaken theory of cytogenesis which these two writers advocated is concerned, this was no doubt justified; but Schleiden and Schwann are usually regarded as the founders of the cell theory in the modern sense without any qualification. Even Haeckel regarded Schleiden as the first to extend the cell theory to plants but the botanists never paid great attention to Schleiden's erroneous discoveries, and it is, therefore, the more remarkable that to Schleiden alone was attributed such an important part in the history of the histology of animals.

Schwann introduced Schleiden's errors into animal histology, reinforced by one of his own, namely, the idea that new cells originate chiefly between the old cells, not within them. On these mistaken ideas (the wrong definition of the cell and erroneous ideas of cell formation) Schwann built up his theory of the "conformity in the structure and the development of the cells in animals and plants". It remained for Max Schultze to correct, twenty-two years later (1861), the errors of Schwann's theory in the sense of Purkinje's ideas.

Anat. Anzeiger, 1927, and *Acta Soc. natur.*, Brno, 1927.

The 'Butterfly' Map Projection

THE problem of reducing the sphere to a plane surface has ever been a difficulty. This realisation has led cartographers to adopt the policy of constructing a map for a specific purpose. The most important features which have to be embodied in maps may be classified in three categories: (1) exactness of shape; (2) exactness of area; (3) exactness of relative position. Whichever of these features will be required is decided by the purpose of the map, and when this has been decided a map is constructed on an appropriate projection. The required feature is embodied in the map, the others are ignored, with the result that distortion in some respect is usually apparent.

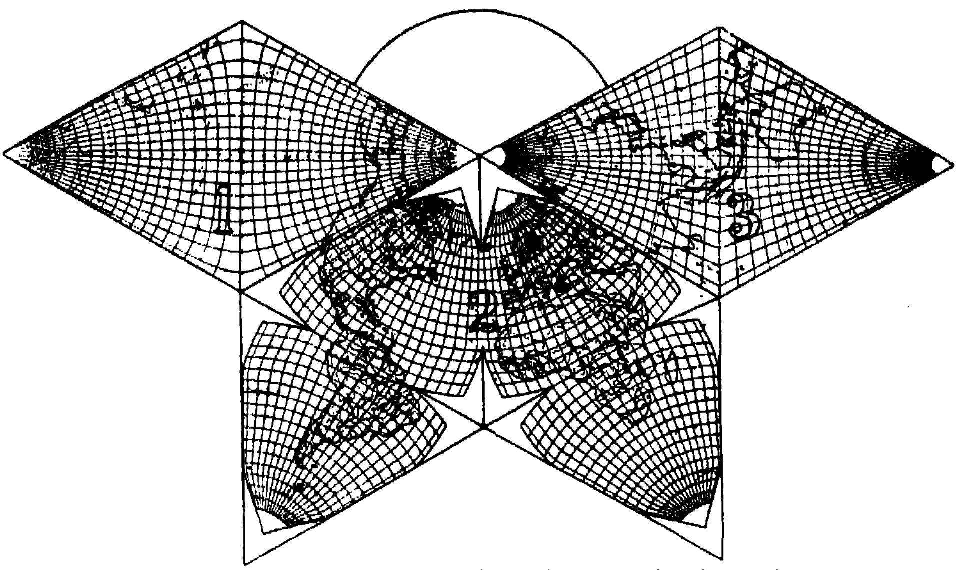

FIG. 1. Butterfly map of the world. The three variants are condensed to one diagram.

Mr. B. J. S. Cahill, of Oakland, California, has regarded this problem from a fresh angle. Instead of making one purpose dictate the form of the whole map, he has realised that in a world map the land areas may be required for one purpose and the water for another. There is also the uneven distribution of land and water over the globe.

The resultant map, constructed to serve many purposes, has been achieved by incorporating various projections into one final form, and by representing the globe by an octahedron (Fig. 1). Such a figure is capable of being more closely approximated to the sphere by the addition, on either face of the octahedron, of smaller tetrahedrons. Thus the principles of triangulation as applied in plane work are translated to the solid. Such an octahedron with tetrahedral modifications can easily be developed into a plane surface.

It must, however, be noticed that such a figure is a substitute for the globe and on development is a spherical representation and not a reproduction. The cube of the gnomonic projection is replaced by this modified octahedron.

The other unusual figure is the combination of various projections, namely, 1, 2 and 3. This gives rise to a grave defect when one remembers that an essential feature of any map is ease of interpretation. A form of projection frequently employed for statistical purposes is that of Mollweide. This is an equal area of projection and when constructed with the Greenwich meridian in the middle of the map, areas in remoter longitudes assume very distorted shapes. To obviate this difficulty the usual form of the projection is replaced by an interrupted form. Against such forms there has always been the accusation that they are not easy to read.

In the case of the 'butterfly' map this criticism will be made, and strongly asserted, because the continuative feature is missing. The faces numbered 2 do not conform to the original octahedral boundaries, whilst the junctions of the portions 1 with 2, 2 with 3 are not too happily made. Such breaches of continuity as are evidenced in tracing the 5° N. latitude and in north-west India (sheets 2 and 3) will require more than supplementing by simple graphic diagrams.

The use of this modified octahedron instead of a single plane is an advantage, but it cannot give a sphere, whilst the discontinuity due to the unhappy alliance of divers projections will scarcely "help mankind to learn to think planetarily".

J. E. COLECLOUGH.

Education and Training for Management

A DISCUSSION arranged by the Department of Industrial Co-operation of the Section of Economic Science and Statistics at the York meeting of the British Association was devoted to the selection, training and placing of administrative personnel, including the study of the "Case Method" as an instrument in education and training for management. The discussion was opened by Mr. Jules Menken, of the Department of Business Administration at the London School of Economics. Mr. Menken described the Case method which was originally developed by the Harvard Business School in the United States. The method is used in many other American schools of business administration as well as at the Business Preparation Centre of the Paris Chamber of Commerce but is little known in Great Britain. Essentially the method consists of the discussion in class of problems actually drawn from business experience. A business case or problem sets forth the facts involved in a particular business situation. It is prepared by the students before they come to class and then forms the basis of a conference or discussion. The student is thus trained to analyse types of business situations, to find principles on which action must be taken in a particular situation, to formulate a plan of action and to justify his policy and plan in reasoned argument.

The successful use of this method depends upon such factors as the selection and training of teaching staff, the development of confidence among the firms associated to secure the provision of material for the cases, and the planning and presentation of the material obtained in a suitable manner. Of fundamental importance is the use of the method with students sufficiently mature in mind and experience to participate in the discussions. The method can be used inductively or deductively but it is relatively unsuited for the teaching of systematised knowledge. Mr. Menken claimed that the method is a valuable instrument for developing a technique of analysis and training the powers of judgment required in business decisions.

The second paper in the discussion was contributed by the Hon. J. F. A. Browne, who outlined some suggestions for co-operation between the universities and industry in the placing of those who have qualified not as specialists such as chemists, engineers, etc., but who have taken a general degree and left the university without a specific vocational qualification. After emphasising the futility of specialised training for business management at the universities, Mr. Browne suggested that it is more important for a man to enter business with a wide general education and a keen mind, trained to learn quickly and accurately, to grasp the essential points of a problem and to analyse a difficult situation. The absence of any agreed demand as to what qualifications are necessary in its recruits, indicates how far industry still is from being professionalised, but industry should regard the universities as a field for recruitment and pay much more attention to machinery for careful and systematic selection of candidates. Bad selection in the past has been largely responsible for much prejudice in industry against university men. Much more of the personal touch is desirable in the work of the Appointments Board particularly in the selection of candidates to be recommended for specified vacancies. Prospective employers should be able to depend on the Appointments Board for a perfectly frank opinion about a man and to regard it as an absolutely reliable source of confidential information. By more careful selection of candidates and particularly by warning them from applying for posts for which they appeared to be unsuitable, the Board could render genuine service to its candidates and prevent the development of an inferiority complex in the minds of those who might otherwise continually apply without success for posts for which they were unsuitable. Efficient selection by the Board, however, depends essentially on industry telling the Appointment Boards frankly what it requires in particular vacancies and in furnishing particulars of the appointment, its duties and prospects comparable in fulness of detail with those supplied by Government regarding Government appointments. Extension of the organised training schemes now being developed by industry is of real value and the Management Research Groups might well explore the possibilities of co-operation in this field, particularly in securing a common approach between different firms and the university appointments boards.

The Wren Tercentenary

THE loan exhibition of portraits, architectural drawings, models, manuscripts, and personal relics illustrative of the life and times of Sir Christopher Wren, brought together in the Trophy Room by the Dean and Chapter of St. Paul's Cathedral, is now open to the public view, and will undoubtedly ensure large attendances, for Wren is secure in the nation's affectionate regard. Very suitably the opening of the exhibition was undertaken by Sir Frederick Gowland Hopkins, president of the Royal Society, who delivered a brief address dealing with various aspects of Wren's many-sided career.

The catalogue of the exhibits contains 168 entries of objects; happily it does not err on the score of meagre description. It would, perhaps, have been helpful to have supplied such an important issue as this—one doubtless destined to circulate all over the world—with a preface embodying the main events of Wren's life, in particular, at least, the series culminating in his great architectural achievement.

Several portraits of Wren at varying ages are shown. These include the small full-length, attributed to Gascar, 1674–80, from Welbeck Abbey, the portrait in the Sheldonian Theatre, Oxford, presumed to be by Sir James Thornhill (about 1675), the St. Paul's modified copy of the Kneller in the National Portrait Gallery (1711), and the Royal Society's portrait, painter uncertain. There is also the Wren death mask, lent by All Souls' College, Oxford. On a sheet of foolscap size appears the following: "I will give one thousand pounds a yeare. Whithall 20 March $\frac{7}{1678}$. Charles R."—

"I will give two hundred pounds a yeare to begin from Midsommer day last past. July 17, 1678 James."

A wealth of material is illustrative of projects and plans for re-building London, its churches, and public offices, under royal commission. Singular in its interest is the great model and rejected design (in oak and other media, and now in complete repair) submitted to the King for a new St. Paul's. A copy is exhibited of Willis's "Anatomy of the Brain" (1664). Though the plates are unsigned they were the work of Wren, as stated by Willis in the preface. It remains to add to this brief notice of some of the many objects displayed that the unique "heir-loom" copy of "Parentalia" (Memoirs of the Family of the Wrens, 1750) is exhibited. This copy descended in the family of Wren, ultimately, by purchase, passing into the ownership of the Royal Institute of British Architects.

From the earliest inception of the Royal Society, and onwards, Wren had been a faithful coadjutor in many ways, a councillor strenuous in effort, prompt in action. On St. Andrew's Day, November 30, 1680, the date of the anniversary meeting (held at Gresham College) for the election of a president and council, it appears that Wren had been re-nominated for membership of council, in company with others. A new incoming member, no other than Robert Boyle, the illustrious philosopher, was chosen as president to follow Sir Joseph Williamson. However, the unexpected happened, for Boyle, in a letter to Robert Hooke, declined office, respectfully desiring the Society to proceed afresh. Whereupon, without any dissentient, Sir Christopher Wren was elected, and he was continued in the post at the anniversary meeting of the year following.

Our existing cordial relations with Sweden are curiously reminiscent of that remote gathering. It is recorded that whilst the lists were being collected, M. Lyenbergh, envoy from the King of Sweden, presented a letter and two books from Dr. Olaus Rudbeck, professor of anatomy at Uppsala, Sweden, for which the president returned the Society's thanks to the envoy. Both communications engaged discussion at a subsequent meeting.

University and Educational Intelligence

CAMBRIDGE.—The professor of physiology has, with the approval of the General Board, appointed G. S. Adair, of King's College, an assistant director of physiological research.

The Cavendish professor of experimental physics gives notice that the Clerk Maxwell Scholarship will be vacant in December 1932. Candidates are requested to send in their applications to Lord Rutherford, at the Cavendish Laboratory, on or before November 1.

At Trinity College Mr. H. Davenport and Mr. G. A. Millikan have been elected into fellowships.

ST. ANDREWS.—An extensive addition has been made to the Bute medical buildings in the form of a new block to house the Departments of Botany and Geology, zoology taking over the accommodation vacated by botany. The new building is of stone and has a dignified appearance, combining harmoniously with its surroundings. The ground floor is occupied by the Botany Department and comprises a lecture room, which will accommodate seventy students, laboratories, research rooms and herbarium. Above are the classrooms of the Geology Department, together with laboratories for palaeontology, mineralogy and petrology. Excellent facilities are available for research both in the building and in the country round St. Andrews.

The work of the Departments of Chemistry and Natural Philosophy was handicapped last session on account of the fire on November 3. Reconstruction and alteration have now been completed, and improvements have been made in the physical and chemical laboratories. A good-sized honours laboratory has been provided at the top of the main staircase for students of physics, and the accommodation for physical chemistry has been much improved. Mr. Donald Mills was the architect for all these buildings.

RESEARCH in higher education is recognised and encouraged by the United States Office of Education as of fundamental importance at the present time and the first of a series of official bulletins on the subject has recently been issued by the Government Printing Office. This reproduces eleven papers read at a conference held last year under the joint auspices of the Office of Education and the University of Oregon. Some years ago this University instituted an elaborate investigation of the methods by which university teaching might be improved. A five-year experimental programme was prepared and a faculty committee proceeded to carry it out. In the papers now published are summarised some of the results grouped under the headings "Instruments of Measurement" (for example, marking systems and types of examination), "Student Personnel Studies" and "Administrative Measures Based on Test Results". Under the second of these are included some interesting accounts of "orientation" and "how-to-study" courses designed as safeguards against the waste of time and discouragement which, in the absence of a tutorial system, are too often experienced by students on passing from school to university, while they are adjusting themselves to the changed conditions of life and study. Such courses, consisting mainly of assigned reading, discussion, some lectures with drill in note-taking, and a large amount of specific drill in approved methods of study and economies in the use of time, have been provided at Oregon since 1927 and their results have been carefully watched and evaluated both subjectively (collecting students' opinions) and objectively—by comparing academic records of students who had participated in the course with those of 'control' groups who had not.

Calendar of Geographical Exploration

Oct. 25, 1616 —West Coast of Australia

Dirk Hartogszoon reached the island still known as Dirk Hartog Island and sailed northward along the west coast of Australia from $26\frac{1}{2}°$ to 23° S. In 1696 de Vlamingh, in the course of an important survey of the coast, during which the islands fringing Shark's Bay were discovered, found a pewter plate set up by Hartog on his visit. De Vlamingh also visited the Swan River, so named from its black swans.

Oct. 26, 1776.—South-west United States

Two Franciscan friars, Fathers Escalante and Dominguez, reached the Colorado River on their return from a journey begun in Santa Fé in July. They set out with the aim of opening up an overland route from northern Mexico to the Pacific seaboard.

They failed in this, but their journey was the most important achievement in the south-west of what is now the United States until the beginning of the nineteenth century. From Santa Fé they went north-west, crossing the upper Rio Grande and entering the basin of the Colorado. They reached the head waters of the San Juan, its eastern tributary, crossed the plateau region between it and the upper Colorado and traced part of the course of the Rio Dolores. They visited the Yuta (Utah) Indians and arrived in the territory of the Comanche Indians after crossing the Green River. A difficult mountain traverse brought them to Utah Lake, which discharges northwards into the Great Salt Lake. This journey marks the farthest advance of the Spaniards in the interior of North America; it was not followed up, fur hunters and adventurers from the United States being the first to make their way into the region of the Great Salt Lake. Escalante's narrative gave useful information about the climate, products and peoples of the region.

Oct. 29, 1762.—Niebuhr in Yemen

A party of Danish scientific workers, among whom was Carsten Niebuhr, a mathematician and practical surveyor, arrived at Jidda in a pilgrim ship. There they remained for two months before they could get a barque to take them on to Yemen, and they passed the time in making observations on the country inland. The party broke up at Beit el-Fakih, and between them covered most of the Tehema southwards to Tais and Zebid and the lower mountains. They were able to travel unmolested in a country afterwards noted for its fanaticism until they reached Mokha. Three of them reached Sana in July, 1763, but they were ill, and two had died; they decided to return, two of them dying on the voyage. Niebuhr was in Arabia again in 1765. Sana, his farthest point inland, is less than a hundred miles from the Red Sea coast, and he explored but a small region. Yet the insight he showed and the careful and faithful delineation of what he saw have made his work a classic still valuable to the student and would-be traveller in the Yemen.

Societies and Academies

London

Society of Public Analysts, Oct. 5.—E. Hinks: Third report of the Milk Products Sub-Committee: The analysis of sweetened condensed milk in which the sucrose has altered during storage. The problem was at first thought to be one merely of determining invert sugar, but by the study of 'aged' sweetened condensed milk by various processes, a modified Barfoed process, copper reduction processes, and in particular a combination of the polarimetric and chloramine-T-iodide oxidation, it was found that the usual hydrolysis products of sucrose present, if any, were dextrose, lævulose and lævan, the proportion of dextrose being sometimes as high as nine or ten times that of lævulose.—**E. B. Hughes**: A new copper reagent for sugar determinations. This reagent consists of copper acetate (5 gm.) mixed with triethanolamine (5 gm.) and made up with water to 100 c.c. The reagent has selective reducing properties; its action on dextrose is appreciable; its action on lævulose is very much greater, and it is only negligibly active towards sucrose, lactose and maltose. By modifying the formula (also by purifying the triethanolamine) the reagent can be made to react strongly with lævulose, but not to oxidise dextrose.—**W. G. Moffitt**: A colorimetric method for the determination of chloroform. The blue colour reactions given by chloroform with α- or β-naphthol in a strong solution of sodium hydroxide have been made the basis of a rapid colorimetric method of determining chloroform. None of the seven chloro compounds tried (including carbon tetrachloride) was found to have any appreciable influence on the reaction with β-naphthol, although α-naphthol gives a blue coloration with carbon tetrachloride under the conditions of the test.

Melbourne

Royal Society of Victoria, Aug. 11.—Leo W. Stach: Victorian Tertiary Polyzoa. (2)—Catenicellidæ. A review of this typically Australian group of the Polyzoa and a suggested new subdivision into three subfamilies, based on the position of the ovicell on the zoarium. This paper discusses the new subfamily Vittaticellinæ and correlates ovicelled zooecia described as distinct species with previously described forms.

Rome

Royal National Academy of the Lincei, May 1.—G. Armellini: The increment of the eccentricity in the problem of two bodies of diminishing mass, with applications to the orbits of binary stars. For a system consisting of a satellite and a principal star, it has been shown that, if the mass of the system is a decreasing function of the time, the mean orbital distance is an increasing function of the time. Some authors consider that, under these conditions, the eccentricity remains virtually constant, but it is now shown that this view is inaccurate.—**U. Broggi**: Series of factorials and equations to the differences.—**R. Caccioppoli**: Linear functionals in the field of analytic functions.—**A. Mambriani**: The summability of Fourier's double series of discontinuous functions.—**T. Boggio**: A theorem of Siacci for the motion along a curve.—**A. Consiglio**: A revolving elliptical obstacle invested by an irrotational plane current.—**G. Agamennone**: The reflection of seismic waves at the antipodes as a cause of earthquake shocks. An attempt was made by Oddone in 1907 to prove that seismic waves, generated by a violent earthquake shock, may be propagated along the earth's diameter to be reflected back along their path and thus give rise to a shock of less intensity than that of the original shock; a second such reflection, giving another shock, was also considered possible. Various difficulties involved in such hypothesis are now discussed.—**B. Rossi**: Secondary effects of penetrating corpuscular radiation. In traversing matter, the corpuscles of penetrating radiation generate a secondary radiation, probably also corpuscular. The number of such secondary corpuscles generated in iron is only about one-half of the number generated in lead and is less than would correspond with the ratio between the two densities. The penetration in iron is, however, about three times that in lead, so that the number of secondary rays in equilibrium with the penetrating corpuscular radiation should be somewhat greater in iron than in lead.—**B. Rossi and B. Crinò**: Anomalies in the absorption of penetrating radiation. Measurements of the absorption in thin lead screens have been made to show the influence of secondary radiation in experiments carried out by the coincidence method

and to indicate how such influence depends on the position of the absorbing screens.—**F. De Carli**: Compounds of urea with alkaline-earth bromides. The solubility isotherms at 11° of the systems, $CaBr_2—CO(NH_2)_2—H_2O$ and $SrBr_2—CO(NH_2)_2—H_2O$ reveal the formation of the compounds, $CaBr_2$, $4CO(NH_2)_2$, $2H_2O$ and $SrBr_2$, $4CO(NH_2)_2$, $2H_2O$, the existence of which in solution is not, however, shown by measurements of the density and fluidity.—**D. Marotta** and **G. Rosanova**: The structure of C-substituted derivatives of barbituric acid. The formation of barbituric acid and its C-substituted derivatives by condensation of malonic acid and its derivatives with carbodiamide indicates for these compounds the structure $CH_2R_2<\frac{CO\cdot NH}{CO\cdot NH}>CO$. Observations on the metallic derivatives of the compounds and their behaviour on fusion with potassium hydroxide raise a doubt as to the accuracy of this constitution.—**B. Monterosso**: Cirrepedological studies (7). Euryalinity and anabiosis in *Chthamalus stellatus* Ranzani. When immersed in fresh water, *C. stellatus depressus* survives for four months at the most and undergoes a partial crisis in its motor activity, but there is no arrest in the relative function and no assumption of a hypnic state (Kreps' *Salzschlaf*).—**M. Sacchetti**: Certain *Zygosaccharomyces*. Copulating yeasts appear to be widely diffused in Nature and a number have been isolated from various Italian products. None of these could be made to sporulate by Hansen's method, but all sporulated on the upper portion of streak cultures on agar or gelatine. To two new species the names *Zygosaccharomyces gracilis italicus* and *Z. felsineus* are given.—**Federico Millosevich**: Obituary notice of Ferruccio Zambonini.

SYDNEY

Royal Society of New South Wales, July 6.—**A. R. Penfold** and **F. R. Morrison**: The occurrence of a number of varieties of *Eucalyptus radiata* (*E. numerosa*) as determined by chemical analysis of the essential oils (1). The several physiological forms of this plant cannot be distinguished on morphological evidence but are readily differentiated by the variation in the chemical composition of the essential oils. The forms can also be separated in the field by crushing the leaves and noting the odours. The chemical evidence in support of the physiological forms is taken from the following data: specific gravity, optical rotation, refractive index at 20° C., composition.—**H. G. Raggatt** and **H. F. Whitworth**: The intrusive igneous rocks of the Muswellbrook—Singleton District. (2) The Savoy Sill, with rock analysis by **W. A. Greig**. This paper describes a large sill-like mass of Tertiary age which intrudes the Greta Coal Measures near Muswellbrook. The intrusion is shown to be a composite sill, the feeding channel of which appears to be partly exposed. The occurrence of two rock types is recognised, one analcite dolerite, and the other soda syenite. An analysis of each of these two types is given and their relationship to each other discussed both from the point of view of petrology and tectonic geology.—**Francis P. Dwyer** and **David P. Mellor**: The crystal structure of indium. While earlier goniometric studies made on electrodeposited crystals of indium have resulted in their assignment to the cubic system, the lines of a powder photograph made with an impure sample of indium have been interpreted as arising from a face-centred tetragonal structure. In order to check the former observations, powder photographs have been made with carefully purified indium deposited on fine silver wires under different conditions of temperature and current density. In none of the photographs was there any indication of a pattern which could be attributed to a cubic space lattice. The face-centred tetragonal structure of Hull was confirmed. The constants found for the lattice were: $a_0 = 4\cdot587$ (0·002A.), $c_0 = 4\cdot954$ (0·002A.), $a:c = 1\cdot078$.

VIENNA

Academy of Sciences, June 23.—**Anton Kailan** and **Rudolf Raff**: Velocities of esterification of alcohols in acetic acid. Velocity constants, and their dependence on the structure of the alcohol, etc., have been determined for the esterification of a number of alcohols by acetic acid.—**Guido Machek**: Action of gaseous cyanogen on phenols (1): Dicyanogen and the three dihydroxybenzenes. Pyrocatechol yields a cyano-derivative, which may be acetylated, benzoylated and methylated, but resorcinol and quinol yield equimolecular additive compounds with dicyanogen.—**Fritz Rieder** and **Elisabeth Rona**: The ranges of the α-rays of actinium products, RdAc, show, besides the main groups with ranges of 4·6 cm. and 4·25 cm., also groups of less intensity with the values 4·5, 4·2, and 4·1 cm. respectively. Ac X shows groups with the ranges 4·0 and 4·55 cm., as well as the principal group (4·2), and Ac C, the two known groups (4·9, 5·39). With Ac Em, the recently discovered subsidiary group (5·2) and a distinct double character of the principal group are noted. Ac A also exhibits signs of complexity (3 groups).—**Gerhard Kirsch** and **Fritz Rieder**: The neutron emission of beryllium. Investigation of the excitation of the beryllium nucleus to emit neutrons by the Wilson method shows that this is a resonance process, which can be brought about by α-particles with ranges of 35·4, 30·0, 25·3, and about 15 mm. From consideration of the absorption curves it appears necessary to assume that emission of neutrons occurs preferably in the direction of impact of the α-particles and in the opposite direction.—**Marietta Blau** and **Herta Wambacher**: The behaviour of a granule-free emulsion towards α-particles. The blackening of such an emulsion by α-particles follows laws different from those holding for the blackening of ordinary photographic films.—**Walter Späth**: Spectrographic detection of very small quantities of substance. The smallest quantities (in grams) detectable are, by the spark method: 10^{-10} Cd, 10^{-10} Mn, 10^{-7} As, 10^{-7} Te, 10^{-8} Tl, 10^{-11} Sr and 10^{-9} Li, and by the arc method, 10^{-10} Cd, 10^{-9} Te, 10^{-9} Tl and 10^{-8} Mn.—**Roman Lucerna**: History of the development of the Matterhorn (4482 metres).—**H. K. Barrenscheen** and **Johannes Pany**: The rôle of phosphation in the intermediate carbohydrate metabolism of plants (2). Assimilating *Elodea canadensis* yields a hexosemonophosphoric acid which belongs to the levulose series but is different from Neuberg's ester. From germinating wheat a phosphated octa-amylose may be isolated and the action of taka-diastase on this also gives a hexosemonophosphoric acid of the levulose series. Partial degradation of an artificially phosphated starch by means of taka-diastase results in a phosphated octa-amylose identical with that derived from seedlings.—**H. K. Barrenscheen**, **Johannes Pany**, and **Robert Berger**: Glycogenolysis. Post-mortem glycogenolysis of the liver does not proceed linearly but follows a stepped curve, analogous to that of the

scission of inorganic phosphate, the coupling of the two processes being thus indicated. The glycogenolysis is accompanied by the appearance of a hexosemonophosphoric acid, the amount of which increases most during the period when the liberation of sugar and phosphate is declining. The hexosemonophosphoric acid isolated from rabbit and dog livers is chemically different both from those previously obtained from biological material and from the artificial products.—H. K. Barrenscheen and Béla Vásárhelyi: Glycosis of the blood (2): Pyrophosphate fraction and glycolysis. Except with pig's blood, the content of pyrophosphate in different bloods increases with the glycolytic power. The whole blood and the erythrocytes, and, to a less extent, the serum and plasma, contain an enzyme which effects the scission of inorganic pyrophosphate and is inhibited by fluoride.—H. K. Barrenscheen and Karl Braun: Glycolysis of the blood (3): Restriction of glycolysis. The pyrophosphate fraction seems to contain an essential part of the co-enzyme effecting glycolysis.—H. K. Barrenscheen, Karl Braun, and Miklos Dreguss: Inhibition of glycolysis and accumulation of methylglyoxal.—H. K. Barrenscheen and Karl Braun: Colour and precipitation reactions of methylglyoxal.—H. K. Barrenscheen and Miklos Dreguss: Colorimetric micro-method for determining methylglyoxal. By separating the bis-hydrazone formed with 2:4-dinitrophenylhydrazine, results accurate to ± 4 per cent are obtainable.—H. K. Barrenscheen, Karl Braun, and Miklos Dreguss: Inhibition of glycolysis and disappearance of methylglyoxal.—H. K. Barrenscheen, Leopold Frey, and Otto Renth: Muscle rigidity and co-enzyme.—H. K. Barrenscheen and Wilhelm Filz: Co-enzyme action (1): Inhibition of glycolysis and liberation of ammonia. The liberation of ammonia appears to be partly responsible for the inactivation of the co-enzyme in glycolysis.—Franz M. Kuen: Oxidation of sugar by atmospheric oxygen and hydrogen peroxide.

Forthcoming Events

TUESDAY, OCT. 25

ROYAL ANTHROPOLOGICAL INSTITUTE.—Dr. P. V. van Stein Callenfels: "Some Early Migrations in the Far East", at 8.30 P.M.

FRIDAY, OCT. 28

The Patents and Designs Act, 1932

THE new Patents and Designs Act, which comes into force on November 1, represents a serious attempt to remedy some of the outstanding defects of the patent system of Great Britain. The importance of the Act at the present time is due to the close relation, too little understood by politicians and administrators, that exists between invention and unemployment. A good patent system promotes employment by fostering inventions of the 'originative' class, which create new demands and so absorb labour, while it has little effect, one way or the other, on inventions of the 'intensive' class, which cheapen the production of existing commodities and so tend to displace labour. A bad patent system, on the other hand, is a fetter on the limbs of industry and an instrument of blackmail.

The present Act marks a definite advance, and the credit for it must go primarily to the British Science Guild. As the sequel to certain articles that had appeared in NATURE, the Guild appointed a strong committee in April 1927, "to consider what changes could advantageously be made in the British patent law", Dr. W. H. Eccles being chairman and Capt. C. W. Hume, honorary secretary. The report of this Committee, published in October 1928, was very widely discussed, and further reports, based upon it, were prepared on behalf of the General Council of the Bar, a joint committee representing the chemical industry, the Chartered Institute of Patent Agents, and a number of other bodies. In May 1929 the Board of Trade appointed a departmental committee under the chairmanship of Sir Charles Sargant to go into the whole matter, taking the British Science Guild's report as the basis of its discussions. The present Act embodies the findings of the latter Committee, and few pieces of legislation can have been subjected to more extensive expert scrutiny before being passed. Lord Marks remarked at the second reading in the House of Lords : "The bill comes to us from the committee who for sixteen months, with the assistance [*sic*] of the British Science Guild, gave very great attention to this very difficult matter with the object of finding a remedy. Subsequently another committee sat for twenty-six months dealing with the same matter, so that we have in fact a bill which has been, in effect, before a Select Committee for three and a half years."

Whether the new Act achieves a substantial

part of the purpose underlying the British Science Guild's report will depend very largely on the manner in which it is administered. If the Board of Trade is endowed with enterprise and vision, it will seize this opportunity of making British patents the most valuable and trustiest in the world, and so of encouraging the investment of capital under their shelter.

At the very worst, the improvement in efficiency and smooth working entailed by the Act marks a substantial gain. It is unnecessary here to enter fully into the numerous and highly technical changes that have been introduced. In one instance—the remedy against unjustifiable threats based on alleged patent rights—the Act prescribes even stronger remedies than the Guild thought it politic to suggest. Appeals from the Comptroller's decisions will in future go to a High Court judge specially appointed. Nugatory inventions, such as perpetual motion machines, will no longer be patentable. Anomalies and inconveniences arising out of the procedure under the International Convention have been removed. The Act also remedies an important defect that was missed by the Guild's committee—the notorious Section 32 A, which fostered the introduction of absurdly wide claims into specifications. These and many other changes introduced by the Act are definitely to the good.

A more important aim of the British Science Guild, however, and a policy that has always been advocated in these columns, has been to check the grant of invalid patents. In the grant by the Crown of monopolies that are legally invalid lies the root of the most undesirable features of the patent system. The new Act has not dealt very courageously with this problem, but it has allotted to the administration one discretion which, if exercised with vigour and wisdom, will yet make the British patent one of the safest in which a man can invest. The principal source of invalidity in patents is want of novelty. To test the novelty of inventions, the Patent Office has since 1905 made a search amongst British patent specifications, and by doing so it has greatly improved the status of British patents and diminished the facilities afforded to that form of blackmail which depends on the unscrupulous (or unintentional) use of invalid patents. Now, however, for the first time the examiners are given discretion to make a search, like those which are made in Germany and the United States, in technical periodicals, foreign specifications, and other published documents. Will this discretion be exercised, or will the great opportunity afforded by the Act be thrown away?

In the articles in NATURE from which the reform movement originated* it was estimated that a very thorough search of this kind would cost at least £120,000 a year, but it was pointed out that this sum could be provided mainly by the surplus of patent fees which is annually taken away from the Patent Office by the Treasury. Since that date, the annual surplus has risen to between £140,000 and £150,000, and moreover, under the new Act, the application fee is being raised by £1 for each complete specification. The principle underlying the Statute of Monopolies was that it is wrong for the Crown to look upon monopolies as a normal source of revenue. Monopolies for inventions were allowed for the sole reason that they encouraged new manufactures: but the use of them for raising revenue is certainly against the spirit of the constitution. The purpose of the patent system is to encourage inventions, not to raise revenue out of them. The surplus revenue from this source ought to be returned to industry in improved services.

However that may be, the inventor will expect full measure for his additional £1 of fees. He waits with some little anxiety to see how it will be expended. Here is a great opportunity to improve the status of the British patent. Is it appreciated? Will it be seized upon with statesmanlike understanding and foresight? Or will these troublesome men of science, who have clamoured so obstreperously for mysterious improvements relating to the encouragement of invention, be thrown just so much of a dry bone as may serve as an excuse for refusing them a fair meal? It is not unreasonable to feel some perturbation on this point. The recent report on the Post Office shows that British commerce has been prejudiced because Whitehall, having little insight into technical mysteries, could see nothing in the communication services but a possible source of revenue. In mixed metaphor, 'the goose that laid the golden eggs was milked of its last drop of blood.' Now the function of the Patent Office is not to produce revenue but to foster new industries by giving to capitalists and investors a justifiable feeling of confidence in the security of British patents. Will it be deprived, as the Post Office was, of the means for carrying out its new duties efficiently?

Brighter Babies

An Outline for Boys and Girls and their Parents. Edited by Naomi Mitchison. Pp. xi+916. (London: Victor Gollancz, Ltd., 1932.) 8*s*. 6*d*. net.

IF the plethora of encyclopædic outlines published during the past decade is a welcome indication of a growing demand for scientific knowledge, it is doubtful whether it shows a widespread understanding of what the scientific outlook is. It is still more doubtful whether many of their authors are capable of communicating the scientific outlook in the way which Kelvin, Tyndall and some of the foremost expositors of the nineteenth century attempted to do. The prevailing fashion in scientific exposition is to conduct a Cook's tour round the outer and most thinly peopled fringe of the universe of science, leaving the holiday-maker in complete ignorance of the populous cities and well charted roads of the older countries. The practice of doing so has partly arisen because scientific writers who are in a muddle themselves find it helpful to explain their difficulties to a sympathetic and appreciative, if somewhat bewildered, audience. The audience knowing nothing of the vast territory of experimental knowledge which lies behind the proliferation of contemporary hypotheses is fitly impressed. The man of science takes the place of the priest and the successful magician. Kelvin's way was different. His addresses are no spectacular display of the latest and least digested marvels of science. He could be content to select a few of the more homely and firmly established truths of science, leading his audience up to the table and showing them that there is a real rabbit in a quite ordinary hat. As all conjurers know, mystification is more remunerative than straightforward explanation. Publishers have discovered the same truth. For those who enjoy the thrill of being mystified Mrs. Mitchison's collection of contributions from twenty-three authors will provide a powerful magic.

This does not mean that the book is without merit. To avoid confusing the persons it is necessary to divide the substance. Only a third of the book is devoted to natural science. An outline of all human knowledge in nine hundred pages for children and parents alike might conceivably attempt three tasks. One is to communicate to the adolescent what the scientific outlook involves. One is to awaken in the child an intelligent recognition of social obligations. A third and necessary evil, since it is what most publishers prefer to print, is to provide gossip for adults who move in circles where it is fashionable to talk most about what is least understood. The latest undertaking of Messrs. Gollancz strives to fulfil all of these. John Pilley contributes a sensible statement about the nature of scientific laws for those who already know what scientific laws are. Olaf Stapledon discusses (with refreshing sanity) the chaos of a world which is rushing from one financial crisis to another. Dr. Strauss illustrates what he means by psychology with the assistance of a picture in which the human mind is made to look like an iceberg. The illustration is reminiscent of the visions of St. Hildegarde and the text is the spiritual co-twin of the tableau.

Of the three parts into which the book is divided the middle one, dealing with civilisation, is most clearly written for children by writers who have some conception of how much a child of average intelligence can digest. Parents who sympathise with the sane and generous perspective of the contributors will think that the book is well worth buying for the sections by Margaret Cole, Lancelot Beales, Gerald Heard and Olaf Stapledon. Hugh Gateskill is to be congratulated upon having written an intelligible account of money. Those who want their children to grow up with a red blooded 'he-creed' need not be discouraged. They can turn to an earlier article in which eugenics is expounded as the belief that "it would be better if the most successful people had most children". Taken as a whole, the book is too well balanced as a commercial venture to be wrecked by the social intelligence of those who contribute to the second part. The third division illustrates the thesis of some of the articles in the second by showing how intellectuals create the demand for the commodities which they wish to sell.

The first part, which covers the whole of natural science in three hundred and eighty-five pages, raises the greatest expectations. There is no difficulty in deciding which parts are intended for children and which for their parents. The biographical sketches at the beginning of each article are suitable for a backward and ailing child of eight. What follows can sometimes be understood by a university graduate. Among those who have no practical experience of education it is a common delusion that intrinsically

difficult intellectual tasks are somehow facilitated by baby talk. So we read that Richard Hughes "can invent wonderful games. He is rather younger than *me* and has very bright blue eyes" (italics inserted). A few pages later this occurs:

"There are three Pure-Number-Ratios. The simplest is $\frac{M}{m}$: the ratio, that is to say, of the mass of the proton to the mass of the electron (it is about 1,750 times as big). The other two are more complicated: $\frac{2\pi e^2}{hc}$, called the 'fine structure constant', and $\frac{e^2}{GM^2}$ which compares the electric and gravitational forces between two protons."

If scientific knowledge is nothing more than verbal assent to a religious creed or an artistic dogma, the scientific part of Mrs. Mitchison's anthology is above criticism. Parents who live in the suburbs will find in it all the passwords they require, when they visit their relatives in Bloomsbury. If scientific knowledge is an understanding of the path traversed in the process of discovery, it is a monument of educational blunders. It is a verbal statement of the latest conclusions of scientists divorced from the practical basis of any well-established scientific truth. In other words, it magnifies all the defects of science teaching in the school. The chief defects of science teaching at present reside in failure to arrange the subject matter presented in stages adapted to the logical equipment of the learner and failure to adapt the logical technique which the learner acquires in the study of mathematics to the scientific problems which emerge in the laboratory. At present the divorce between symbolism and experience is so grotesque that a constructive educationist would welcome the opportunity of contributing to an outline from which a child might learn good reasons for persevering in some of the apparently useless tasks presented by the school curriculum.

The naturalistic portion begins with an all too short historical survey by Dr. Singer and his wife, followed by two intelligible chapters upon biology. Biology is split into two sections called physiology and biology, as if the latter did not include the former. Chemistry follows. After that there is a section upon mathematics, physics and astronomy treated together. For this order of treatment much might be said. Modern chemistry has some of its roots in the study of respiration. So has the generalised doctrine of the conservation of energy. The study of the constant relation between chemical output and animal heat in the experiments of Laplace and Lavoiser might lead naturally to the search for some measure of mechanical activity with a definite relation to heat production. This opens a safer experimental route to the notion of work than the traditional method employed in teaching mechanics to pupils without a knowledge of the calculus. Adopting this approach, the instructor might be congratulated if a fairly bright child of fifteen succeeded in carrying away a clear understanding of what energy means and why we believe in the atomic structure of matter. Few, if any, with practical experience of education would hope to surpass an achievement so praiseworthy.

The contributors to this "Outline" have other ambitions for their children. These bright babies—bless them—can grasp in two pages that atoms exist. Then they plunge into X-ray analysis and are soon wallowing in "energy-levels". The brighter babies have no difficulty in polishing off energy levels. They already knew all about energy before they read the book. It was not necessary to insult their intelligences by explaining what energy is. So they can trip lightly on to residual forces (p. 296). They reach the Michelson-Morley experiment on p. 314, and pause five pages later to study the implications of Planck's constant. This offers no insuperable obstacle. "John Pilley has told you that the electrons belong in energy levels." Refreshed with a little baby talk they can face the Cepheid variables on p. 335 and digest the Fitzgerald contraction on p. 340. Leaving on one side the Arithmetic Continuum on p. 354, while noting that "π can never be the solution of an algebraic equation", they toy awhile with imaginary numbers. The theory of a complex variable is expounded off on p. 354. After that they are ready to sleep peacefully upon Cantor's unresolved paradox of the last of all transfinite numbers. This takes up the greater part of p. 355.

If this is what the children of the most "successful" people can really understand, there is something to be said for eugenics. A scientific editor equipped with a good knowledge of the history of mathematics and a modest recognition of the fact that education is a skilled job, might have made a constructive contribution of great importance to the task of reforming present methods of science teaching in the school. Instead, the articles

which deal with the physical and mathematical branches of modern science in this outline can only add to the number of children who think that algebra and geometry are mysterious and terrifying branches of poetry with no applications to everyday life. The scientific articles represent a conception of education which is the consistent outcome of an idealistic orientation. For after all, the materialistic outlook, as one much abused philosopher of the nineteenth century remarked, is "the unity of theory and praxis".

LANCELOT HOGBEN.

Elementary Modern Physics

(1) *Electrons and Waves: an Introduction to Atomic Physics*. By Prof. H. Stanley Allen. Pp. viii + 336. (London: Macmillan and Co., Ltd., 1932.) 8*s*. 6*d*.

(2) *Matière et atomes*. Par Prof. A. Berthoud. (Encyclopédie scientifique: Bibliothèque d'histoire et de philosophie des sciences.) Deuxième édition revue et augmentée des "Nouvelles conceptions de la matière et de l'atome". Pp. vii + 324. (Paris: G. Doin et Cie, 1932.) 26 francs.

(1) A SHORT book like this on modern physics, sufficiently technical to make it of use as an introduction to advanced work for a university degree, but easy enough to be comprehensible for more general readers, has been wanted for some time. Its plan is to show the development of those parts of physics which are now of special interest, from ancient times, but to do little more than refer to the older work, and to give quite full accounts of certain aspects of current and recent research. In this way, the interest of the history of the subject has not been entirely lost, but the interconnexions of various parts which have only recently appeared have been kept continually to the foreground

The ground covered is atomicity, relativity, radioactivity, and the old and new quantum theories. The detail presented can be gauged from the index of sixteen pages of small print, but the charm of Prof. Allen's style is such that after reading the book, the fact that it contains so much comes as a surprise. The book is based on lectures delivered in the University of St. Andrews, and the last chapter, a summary of the others, contains the substance of a supplement to NATURE for Dec. 8, 1928. Illustrations are numerous and well-chosen.

One naturally inquires how far Prof. Allen has met in advance the problems which this work presents to a careful reader approaching it for the first time. This he appears to have done unusually well, very largely by introducing a number of apposite quotations from other authors, some of considerable length. In connexion with the general theory of relativity, one notices that the fiction of the freely falling lift has again been employed; this is not an entirely happy illustration, as the process to be visualised is not a common experience, and the whole difficulty with beginners at relativity is, as Prof. Allen realises, to obtain anything more than polite assent to the propositions. Could not the lift be replaced to advantage with something more vivid, for example, a falling aeroplane? In the matter of general presentation, the only criticism which is offered is that perhaps insufficient stress has been put upon the extent to which physics advances through measurements of high precision —in particular, through the accurate work possible with comparatively simple spectroscopic apparatus; some account of, say, H. N. Russell's work on the spectrum of titanium would not have been out of place, and, after all, the process of finding terms in a spectrum has more than a little in common with the solving of cross-word puzzles.

There is a misprint on p. 278, *l* being used for 1 in the table. On p. 193 there is some confusion, not serious, between the different forms of Geiger counters. Philosophers will also certainly quarrel with some of Prof. Allen's remarks and quotations, although to a physicist they are very interesting. These points are, however, trivial, and do not detract from the value of the book, which is likely to be widely read.

(2) The aim of this book is similar to that of "Electrons and Waves". It is the second edition of Prof. Berthoud's "Nouvelles conceptions de la matière et de l'atome" (1923), with a change in title to avoid the implication that it is chiefly concerned with the new quantum mechanics. This is dealt with in an additional chapter, and in all, about half the volume rewritten. Compared with Prof. Allen's book, it covers less ground, but is rather more pretentious mathematically; there is less philosophy, but more space given to the properties of atoms which find expression in the periodic table, as is to be expected with the author a physical chemist. In style, Prof. Berthoud is more dogmatic than Prof. Allen, but still very interesting. The two books can well be read together, and, at the very lowest estimate, Prof. Berthoud's is a good introduction to French scientific literature.

K. G. E.

The Place of Origin of Yellow Fever

Yellow Fever: an Epidemiological and Historical Study of its Place of Origin. By Dr. Henry Rose Carter. Edited by Laura Armistead Carter and Wade Hampton Frost. Pp. xii + 308. (Baltimore, Md.: The Williams and Wilkins Co.; London: Baillière, Tindall and Cox, 1931.) 26*s*. 6*d*. net.

THE history of yellow fever, notorious for the dramatic suddenness of its outbreaks, and for two centuries an ever-present terror to the crews of old sailing ships, and the coastal towns on both sides of the Atlantic, as might have been expected, has attracted the attention of many writers. Most of these histories, however, were written before the method of transmission of the disease had been discovered; consequently it was very desirable that these earlier accounts of epidemics should be re-examined in the light of more exact information as to the epidemiology of yellow fever. The early history of the disease has now been very carefully investigated by Henry Rose Carter, a well-known authority, who after retiring from the position of assistant surgeon-general in the United States Public Health Service, devoted the last three years of his life to this subject. At his death in 1925, the present work had been fully drafted, but it has been prepared for publication, with some additions, by L. A. Carter and W. H. Frost. The result is a fascinating account of a subject interwoven with the early history of all maritime nations, since yellow fever is essentially a disease of seaports and ships.

The first part of the book is devoted to the epidemiology of the disease, including recent work on the subject; the second part to maladies which have, or might have, been confused with yellow fever in the past; and the third, and greater part of the book, to the place of origin of yellow fever.

Spirochætal jaundice, or Weil's disease, is a serious omission from the long list of diseases that have been confused with yellow fever, since it has been mistaken for this malady up to very recent times, the most notable example of this error being the cases from which Noguchi isolated "*Leptospira icteroides*", the supposed causative agent of yellow fever. It is now clear that these must have been cases of Weil's disease, erroneously diagnosed as yellow fever, since the etiological agent of the latter has been shown to belong to the rapidly increasing group of filterable viruses.

The place of origin of yellow fever resolves itself into a discussion of the rival claims of the only two regions in which it is known to have become permanently endemic—tropical America and West Africa. Although many epidemics have been recorded in western Europe, since the first European outbreak in Cadiz in 1730, there is no evidence that the disease ever became permanently established in this region. The majority of writers in the past, with the notable exceptions of Sir James Kingston Fowler, Sir Robert Boyce and other members of the British West African Yellow Fever Commission, have generally assumed that yellow fever was introduced to the Old World from America, but in recent times evidence has been accumulating to show that West Africa is the original home of the disease. The author discusses the data on this problem under two headings, biological and historical. With regard to the former, it is pointed out that the West African negro possesses a certain tolerance toward the disease, in contrast with the American Indian, who is as susceptible as a white man. The main vector of the disease, *Aëdes* (*Stegomyia*) *aegypti*, has no near American relatives, but many in Africa, a strong argument in support of the view that the yellow fever mosquito was originally an African species, which has been carried in ships to all parts of the world where favourable breeding places and suitable temperatures were present.

The historical evidence is next considered and includes the most interesting chapters of the book. Starting with the assumption that the disease, together with the transmitting mosquitoes, was carried across on ships travelling between West Africa and tropical America, it is shown that a brisk slave trade sprung up between these two regions soon after the discovery of America, for although the first general licence for this trade to the Spanish Indies was not issued (by Charles V) until 1516, already in 1503 the Governor of Hispaniola, Ovando, complained that too many negroes had been admitted for good order. The author then examines the early Mexican records, contained in the hieroglyphic manuscripts or codices, and the writings of the earlier Spanish historians, and shows that, from the symptoms, the epidemics described among the ancient Mexicans could not have been yellow fever, a view supported by the absence of any disease of this nature from the earlier Spanish troops. The Maya records also provide negative evidence for the 120 years previous to 1648, when the first known epidemic of yellow fever in America occurred in Yucatan

and the French Antilles, followed in 1686 by an epidemic in Bahia.

By excluding the presence of yellow fever from America until after 1648, West Africa is considered to be established as the place of origin, but the historical evidence concerning African epidemics is very incomplete. There have not been the same numbers of white settlers in West Africa as in tropical America, and an endemic disease of this nature might well have passed unnoticed among the numerous other diseases.

Nevertheless, the available historical evidence is consistent with the view, also supported by biological evidence, that the original home of yellow fever is West Africa and not tropical America.

E. HINDLE.

Short Reviews

Allen's Commercial Organic Analysis: a Treatise on the Properties, Modes of Analysis, and Proximate Analytical Examination of the various Organic Chemicals and Products employed in the Arts, Manufactures, Medicine, etc. Vol. 9: *The Proteins of Plants, the Proteins of Milk, Milk, Milk Products, Meat and Meat Products.* By the Editor and the following Contributors: D. Jordan Lloyd, G. D. Elsdon, H. Leffmann and John Golding, E. R. Bolton, C. Robert Moulton. Editor: Dr. C. Ainsworth Mitchell. Fifth edition, revised and partly rewritten. Pp. ix+617. (London: J. and A. Churchill, 1932.) 32*s*.

IN the previous volumes of this comprehensive work, the general aim has been to deal with separate branches of chemistry in a particular volume. Thus, such subjects as sugars, starches, soaps, explosives, essential oils, etc., require less than one volume each, for their detailed study. The subject of protein analysis, however, receives much wider consideration. The proteins generally have been dealt with in the eighth volume and in the present volume of 600 pages the whole book is given over solely to the examination of proteins of plants, milk and meat. This will necessitate the issue of a new volume for special subjects, such as hæmoglobin, albuminoids, structural proteins, etc.

The detailed and specialised information on protein analysis and related subjects given in the volume under review is more exhaustive and the references more complete, than that in any work of a similar nature hitherto published in English. The most recent methods of analysis are given, especially in the sections on milk and meat products, and special emphasis is placed on methods of practical importance.

The work as a whole is remarkably free from errors and the revision has been thorough and accurate. The high standard of the earlier volumes is being maintained.

J. REILLY.

Comparative Ethnographical Studies. Edited by Erland Nordenskiöld. Vol. 9: *Origin of the Indian Civilizations in South America*, by Erland Nordenskiöld; *An Arrow Poison with Cardiac Effect from the New World*, by C. G. Santesson; *The Ancient Peruvian Abacus*, by Henry Wassén. Pp. iv + 205. (Göteborg: Göteborgs Museum; London: Oxford University Press, 1931.) 18*s*. 6*d*. net.

IN this volume of the "Comparative Ethnographical Studies" the main theme, both in respect of the space it occupies and of significance, is the question of diffusion versus independent origin in America. Baron Nordenskiöld examines the Indian cultures of South America in detail with the view of determining how far they have been introduced *ab extra* and how far they have developed on the spot. By means of tables of geographical distribution, he shows that certain elements—a considerable number in fact—have a sufficiently wide range from the north of North America to the extreme south of the southern half of the continent to be regarded as belonging to a basic Indian culture. The variations in South American Indian cultures are, he holds, developments in response to local conditions, for example, the cultures of the tropical belt. Certain elements are distinctive of American culture and must be regarded as local. Such, for example, are the cultivation of domesticated food-plants peculiar to America, and metal working.

The author sets aside, as outside his province, the resemblances which Dr. Rivet sees between the languages of Melanesia and America; but as regards cultural affinity he argues that any introduction from Oceania must be extremely remote, as it must have preceded the introduction into the Pacific of sugar-cane, the banana, fowls and pigs. The argument is supported by a body of detailed evidence which cannot fail to carry great weight.

The Principles of Epidemiology and the Process of Infection. By Dr. C. O. Stallybrass. Pp. xii + 696. (London: George Routledge and Sons, Ltd., 1931.) 30*s*. net.

THIS book, by the chief assistant medical officer of the City and Port of Liverpool, represents an ambitious effort to link up the observational data of epidemiology as closely as possible with the basic facts and theories of immunological science. It contains nearly seven hundred closely written pages interspersed with numerous charts and tables and displays wide and catholic reading on the part of the author, as the bibliography at the close of the book testifies. The wealth of detail with which certain portions of the book dealing with periodicity in disease, statistical studies and methods of prophylaxis are furnished, will prove most useful to interested readers, as such data are not too readily accessible.

We doubt, however, whether the author was wise in attempting to assemble and evaluate the immunological data appropriate for his purpose without the critical aid that only first-hand know-

ledge and experience of the science of immunology can supply. As they stand, the chapters dealing with the basic data must give a somewhat confused picture to health officers to whom the book is chiefly addressed, and to the bacteriologist some feeling of irritation at the mishandling of his archives. In spite of these faults, the book is a veritable mine of information on epidemiological data of every kind and will, we are sure, prove a highly appreciated work of reference. Misspellings, particularly of proper names, are unfortunately rather numerous.

Airgraphics. By Alexander McAdie. Pp. 37 + 7 plates. (Cambridge, Mass.: Harvard University Press; London: Oxford University Press, 1931.) 12*s.* 6*d.* net.

PROF. MCADIE has brought together a number of physical formulæ and conversion tables of interest to meteorologists. There are also diagrams showing various relationships such as that between temperature and height up to a height of about 25,000 metres in different latitudes in summer and winter. But the value of the work must surely be reduced by the absence of a table of contents and of both preface and index. The absence of a preface makes the task of the reviewer a difficult one, the exact purpose of the work being a matter of conjecture. Matters would not be so unsatisfactory if the diagrams were self-explanatory. Fig. 2 is entitled "Kilobar, Kilograd and Kilometer Scales"; there are three curves labelled "pressure", "density" and "temperature"; these words also appear against the horizontal axis, while "kilometers" appears against the vertical axis. The curve for temperature bears no resemblance to average or individual curves for temperature and height in the earth's atmosphere, which seems to negative the idea that the kilometres are heights. The meaning of the figure is a mystery.

The letterpress begins abruptly on an un-numbered page with a long quotation from Shaw's "Manual of Meteorology", followed by a few comments on this quotation. With the next page a comparatively consecutive narrative begins under the heading "Simplifying Symbols"; suggestions are made as to what symbols should be used in meteorology, and numerous conversion tables and physical formulæ follow. The title of the work is not a good clue to its contents, for whereas eighty per cent of it is occupied with these last items, there is no discussion of graphical methods of presenting upper air relationships and the graphs are its weakest feature. E. V. N.

Constitution of Atomic Nuclei and Radioactivity. By G. Gamow. (The International Series of Monographs on Physics.) Pp. viii + 114. (Oxford: Clarendon Press; London: Oxford University Press, 1931.) 10*s.* 6*d.* net.

MR. GAMOW leaves one with a curiously unsatisfied feeling, for in no instance has the quantum theory of the nucleus, his main theme, solved any of the problems encountered with the finality—fictitious, perhaps, but nevertheless apparent—that it has attached to so many other aspects of atoms. The lack of success increases as one moves inwards. Well away from the nucleus, the α-particles and nuclear β-particles and γ-rays are almost old friends with regular habits; the potential barrier which they have to traverse to gain their freedom is also fairly well understood in general terms; but the region within this where they have their origin, which can be studied mainly only by its essentially abnormal conduct when it disintegrates, is largely *terra incognita* still.

Mr. Gamow's book has three principal objects. First, it provides a summary of those results of experiment which are likely to be of the greatest significance in the development of the theory, which proceeds more or less concurrently. In this choice there is naturally a certain amount of individual opinion, but it is doubtful if the selection could have been made better. Evidently much more information is required to test the theory as far even as it has been taken, but it may be confidently expected that recent improvements in technique and the complete working out of the intrusion of optical spectroscopy will provide this before long. Secondly, it develops the initial ideas of Gamow, and of Gurney and Condon, on the properties of the potential barrier, particularly those which are connected with the Geiger-Nuttall law of α-particle ranges; and lastly, and it is here that it is specially important, it contains an examination of the relations likely to exist between the main types of nuclear radiations, both spontaneously and artificially excited, on certain hypotheses, the most fundamental of which is that the extra-nuclear quantum mechanics gives an indication of what may be expected to occur internally.

Mr. Gamow has had the assistance of Miss B. Swirles in the preparation of the English manuscript; the result is a well-written and interesting production, the main faults of which are the absence of an index and of references to other theoretical work.

Microbes and Ultramicrobes: an Account of Bacteria, Viruses and the Bacteriophage. By A. D. Gardner; with an Appendix by G. R. de Beer. (Methuen's Monographs on Biological Subjects.) Pp. viii + 120. (London: Methuen and Co. Ltd., 1931.) 3*s.* 6*d.* net.

DR. GARDNER has added another good biological book to this excellent series. He does not attempt to deal with the whole of microbiology but, after a rather scrappy chapter on the structure and functions of bacteria, he gives good and stimulating accounts of bacterial variation, the ultramicroscopic viruses and the bacteriophage, as up to date as any version of these moving topics can be and adapted for the general biologist as well as the technical specialist. There are a few mistakes; for example, distemper vaccine is not made in guinea-pigs (p. 65). Mr. de Beer adds an appendix pointing out the analogy between genes and viruses.

The Explanation of Animal Behaviour

By REX KNIGHT

PROF. LLOYD MORGAN long ago formulated the principle that "we should not regard any instance of animal behaviour as the outcome of higher mental processes, if it can adequately be interpreted as the outcome of mental processes which stand lower in the order of mental development". This principle is but a special application of the canon of parsimony, which must be obeyed in all scientific explanation; and, when logically extended, it imposes upon us the duty of inquiring, in the first place, whether animal actions must be ascribed to any mental processes at all.

It happens, however, that, if we openly pursue this inquiry, we run the risk of being misunderstood; for many people will wrongly suppose that in suggesting a non-mental explanation of animal behaviour, we are thereby questioning the existence of animal minds. In my much-discussed communication to the British Association at York, for example, I criticised the view that some animal actions cannot be accounted for unless we regard them as caused by the animal's mental experiences; and, in effect, I suggested that the view is unjustified. This was my sole aim, and (since to question whether A is necessary to the explanation of B is not to question whether A exists) it did not imply that there are no animal minds. Moreover, to guard against misunderstanding, I was careful to state, both at the beginning and at the end of my paper, that it is probable, on evolutionary grounds, that animals have mental experiences corresponding to their neural organisation. Nevertheless, I was widely misunderstood, and the general discussion, which newspaper reports of my remarks has aroused, has mostly proceeded on the mistaken assumption that I questioned or denied the existence of animal minds.

Let it be clear, then, that when we inquire whether animal actions can be explained in non-mental terms, the question is not whether animals think, but whether their thoughts must be held to affect some of their actions. What we are asking is this: Even though there be animal minds, must we ascribe causal efficacy to them in order to explain how animals act?

When the layman seeks to produce some animal action, which, in his view, cannot be explained in non-mental terms, he is apt to refer, first of all, to examples of the differentiation that animal behaviour often exhibits. He tells of the cat that will sleep only on one particular cushion, of the dog that attaches itself more to one person than to others, or of some other animal whose behaviour is differentiated. Sir Edward Headlam, for example, wrote to the *Times* (April 5) about a hunter that neighed whenever it saw a pink hunting-coat; and in the same journal (Sept. 24) Mr. H. Boyd Collins told of a dog, which, when its master imperfectly simulated grief, acted in a way in which (so ran the suggestion) it would not have acted if the simulation had been complete. It is urged that in all these cases the animal 'knows', and that its behaviour must be ascribed to conscious discrimination.

This conclusion, however, is unwarranted. The fact that an animal responds differently to two different stimuli may not be due to the animal's having mentally distinguished between them. A wireless set will respond differently to different wave-lengths; a flower will respond differently to light and to darkness; a decapitated earthworm, confined in a T-shaped tube, will keep away from that branch of the T which gives it a mild electric shock; and, if we put a drop of acid on a spinal frog, the brainless creature will scratch just the spot that we touch—and, if we increase the strength of the acid, it will scratch correspondingly harder. Since in none of these cases is there any question of mind, it is clearly illicit to argue that differentiation in behaviour must always be due to conscious discrimination.

A second group of actions, the explanation of which is said to require reference to animal minds, comprises those that are sometimes ascribed to animal memory. Under this head we hear of the cat that purrs when its mistress comes home after a holiday; of the (authentic) elephant that deluged the man who had given it, six weeks before, a sandwich with much cayenne pepper; and of the dogs, referred to by Miss Katherine Buck in the *Morning Post* (Sept. 9) whose death followed, and seemed to be caused by, the previous death of their mate or their master.

But 'memory' is an ambiguous word. We can remember what we did last Sunday, and this kind of memory does involve the mind and conscious recall. We can also remember how to skate or to swim, and here the mind need not enter at all—by saying that we 'remember' we mean merely that the results of certain past behaviour have been enregistered in our bodily system, or (in Pavlovian language) that certain of our inborn reflexes have been interlinked or otherwise conditioned by our environment. Now, no one will dispute that many animal actions are due to memory, in the second, non-mental sense. But can we be reasonably sure that, as Prof. Lloyd Morgan and Sir Arthur Thomson believe, animals enjoy conscious recall? Even if we can be sure of this, are there any animal actions which must be attributed to conscious recall rather than to its physiological counterpart? Clearly, the cat's purring on the return of its mistress demands no such explanation. It can be adequately accounted for by the purely physical traces which the cat's previous association with its mistress has left in its nervous system; and the same may be said of the vindictive elephant. Nor does the death of a dog as the result of the death of its mate or its master need to be ascribed to any mental

experience. After all, a dog will not long survive the absence of food; and, granted that the food-stimulus is one that the dog innately needs, surely the stimuli provided by mate or master may become acquired or conditioned necessities. What affects the bereaved animal may be, not the recollection of past events, but just the absence of the mate or the master from its present environment.

A third group of animal actions, which, it is said, must be due to mental experiences, contains those that arise in connexion with animal learning. Animals, of course, can be trained. Sheep-dogs, horses, elephants, and other animals, are being trained every day; and, under experimental conditions, there has been (to mention only a few examples) the training of Möbius's pike, Yerkes's turtles, Sackett's porcupines, Thorndike's cats, and a large number of colonies of maze-threading rats. But, great as is the practical and theoretical value of animal training, does it anywhere provide us with facts that require the ascription of causal efficacy to animal minds? The training in each case seems clearly to consist in that modification, or conditioning, of the animal's inborn responses which does not demand explanation in other than physiological terms. It exhibits the gradual elimination of wrong responses (wrong in relation to the particular training concerned), and the organisation of right responses into larger and larger units. But it does not necessitate retrospection or any other experience in the animal's mind. There is no need to hold that Pavlov's dogs, when they salivated in response to the ringing of a bell, must have been consciously remembering those earlier occasions when the ringing of the bell had been accompanied by the giving of meat; and all other animal training, being but an extension of this simple case, is similarly explicable in non-mental terms.

Animals, however, do not learn only when they are trained by human beings. They also learn, as we say, 'on their own'. These two forms of learning are, to be sure, not radically different. In both the animal's learning consists in the changing of its behaviour under the influence of environment, and the only distinction between them is that in the first the environment is more controlled by man than it is in the second. Still, it is useful to separate the two forms, for it is when animals learn 'on their own' that the efficacy of their minds is said to be especially obvious.

Many British Association critics of my paper have brought forward examples of this kind of learning. The *Times* has published letters from Mr. C. H. Roberts, who described (Sept. 29) how a dog, finding no one at home to fill its water-bowl, carried the bowl to the house of a neighbour; from Mr. Gilbert Coleridge, who told (Sept. 23) how a pony learned to lift a gate off its hinges; and from Lieut.-Col. W. Bunbury, who gave an account (Sept. 21) of a Cairn terrier's feints. Moreover, both in the *Morning Post* (Sept. 6) and in the *Veterinary Record* (Oct. 1), Sir John Moore described how he fell one day in the hunting field and was hung up by the stirrup between his horse's legs, and how the horse stopped twenty or thirty yards from the fence and put its off hind-leg beside him.

Now, in all these cases we may accept the recorded facts without accepting the view, dogmatically laid down in each instance, that they can be due to nothing but animal reasoning. For my part, before accepting any such view, I should require to know much about each of the examples put forward—more facts about the reported occurrence, and about the past behaviour of the animal concerned. Nevertheless, I would say, even now, that the action of Sir John Moore's horse was not indisputably due, as he supposes, to "reason, memory, and other attributes of mind". The stopping of a horse, whose rider has become suspended between its legs, can quite well be explained in terms of reflexes; and I think a similar explanation would suffice in each of the other cases that have been brought forward.

If I seem here to be over-cautious in regard to the efficacy of animal minds, I have at least two reasons for my parsimony: first, there is abundant evidence that brainless animals can profit by experience—that even the naturally ganglionless starfish learns; secondly, my own observations of animal behaviour, both inside and outside the laboratory, have shown me how easy it is for animals to acquire an undeserved reputation for mental characteristics. In my Department in the University of Aberdeen, we have been making careful observations of animal learning under controlled, experimental conditions. In one of our experiments we observed the behaviour of cats learning to get out of a box which could be opened from the inside only by pulling a stirrup. Most of the cats did learn to pull the stirrup; and one in particular earned a great reputation for intelligence among visitors by the speed with which, after a time, it opened the box and got to the milk that was waiting outside. These casual visitors naturally supposed that the cat pulled the stirrup because it had consciously grasped the fact that its action would open the door. Such a supposition, however, must be discounted in view of the fact that, when the stirrup was moved, the cat still clawed the air in the place where it had been—and that, when placed beside milk outside the open box, the cat would often not touch it until it had needlessly run into the box and pulled the stirrup.

It seems, then, that, when we consider the main groups of animal actions which are said to be caused by animal minds, we find none which is clearly incapable of being explained in non-mental terms; and this was the view that I sought to express and to argue at York.

One word in conclusion. Some of my critics, notably Mr. Gilbert Coleridge (*Times*, Sept. 9) and Sir John Moore (*Veterinary Record*, Oct. 1), condemn the observation of animal behaviour under experimental conditions. In a scientific journal there is no need to rebut so perverse a

view; but I would make just two comments upon it. First, under experimental conditions we can observe the genesis of any particular action, and so avoid those false inferences to which observation of the action by itself might naturally lead. Secondly, under experimental conditions we can compare the behaviour of normal animals with that of spinal or decerebrate preparations, and thus test such mistaken assumptions as that mind is required in order that an animal should respond differently to different stimuli, or be modified by its environment.

Sir John Leslie, 1766–1832

By Prof. D. F. Fraser-Harris

The centenary occurs on November 3 of the death of Sir John Leslie, mathematician and physicist. Leslie was a native of the small town of Largo in Fife, where his father, a most intelligent man who had come from the neighbourhood of St. Andrews, was a cabinet-maker. Leslie's mother's name was Carstairs. When only thirteen years old, John was sent to the University of St. Andrews to study for the ministry of the Church of Scotland, but after six sessions there and one or two years at Edinburgh until 1787, he gave up the idea of the Church and devoted himself to the study of his favourite mathematics. His paper on "The Resolution of Indeterminate Problems" had the honour of being admitted to the *Transactions of the Royal Society of Edinburgh* when its author was as yet in his twenty-second year.

In 1793 appeared Leslie's translation of Buffon's "Natural History of Birds" in nine volumes which he had made for John Murray.

Unsuccessful as a candidate for a chair first at the University of St. Andrews and then at the University of Glasgow, Leslie retired to Largo, where he carried out these experiments which, when published in 1804 as "An Experimental Enquiry into the Nature and Properties of Heat", made his name famous throughout the world of science. In this now classical research, he employed his famous cube to study the relative absorptive and reflecting powers of a large number of materials. The 'differential thermometer' which he had devised some years earlier was now found exceedingly useful. This instrument has been described by an enthusiastic admirer as "one of the most beautiful and delicate that inductive genius ever devised as a help to experimental enquiry". The essay of 1804 won for Leslie the recognition of the Royal Society, the Rumford Medal of which was awarded him in 1805.

In the same year, Leslie was a candidate for the chair of mathematics in the University of Edinburgh, vacant through the translation of Playfair to that of natural philosophy. Leslie, whose testimonials included one from Sir Joseph Banks, was vastly better qualified in science than his only opponent, a minister of Edinburgh; but the clergy, professing to see in his essay 'an infidel note' because he had quoted approvingly some remark of Hume on cause and effect, opposed in the most vehement manner his election to the chair. All intellectual Scotland was in a state of ferment; the case was argued for two days before a court consisting of 180 members and by a majority of only 12 at midnight on the second day was Leslie acquitted of heresy (May 1805).

In 1809 Leslie published his "Elements of Geometry" which saw four editions. In the following year he succeeded in freezing water by artificial evaporation. A quantity of water was placed alongside some sulphuric acid in the receiver of an air-pump from which the air was rapidly removed. This diminution of pressure caused a vigorous evaporation from the water, the vapour being taken up by the acid as fast as it was produced. Leslie's evident joy at seeing the crystals of ice forming in the water has been testified to by an eye-witness. Leslie is therefore the 'father' of refrigerators and all manner of appliances for producing low temperatures. Most of the pieces of apparatus used in these researches were made by Leslie's own hands, and are now carefully preserved in the University of Edinburgh.

In spite of having made these fundamental discoveries in the science of heat, Leslie believed to the last in the objective existence of cold, and, in expressed opposition to Wells, held that dew was the result of "cold pulsations from the azure sky".

In 1819, on the death of Playfair, Leslie was elected to the more congenial chair of natural philosophy.

Clerk Maxwell has told us that Leslie was the first to give the correct explanation of the rise of liquid in a narrow tube by capillary attraction.

Leslie, who had travelled widely and read as widely, was in 1820 elected a *correspondant* of the Paris Academy of Sciences. He was the author of a large number of essays on mathematical and physical subjects, one of the most valuable of which was his "History of Mathematical and Physical Science during the Eighteenth Century" in the seventh edition of the "Encyclopædia Britannica".

Probably Leslie's most celebrated student was Thomas Carlyle, whose ticket, duly signed for the class of mathematics, may still be seen in the Carlyle House, Cheyne Row. Leslie had a high opinion of Carlyle's mathematical powers, and he helped him to his first appointment (1814) as teacher of mathematics in Annan Academy.

In 1832, on the recommendation of Brougham, Leslie was created a knight of the Guelphic Order by King William IV in the illustrious company of William Herschel, Charles Bell and David Brewster.

As a bachelor of frugal habits, Sir John had an income much in excess of his needs so that he was enabled to purchase the estate of Coates near

Largo, to which he used to retire in the long vacation.

In person Sir John Leslie was of short stature and very corpulent, with protruding upper teeth, of florid complexion and rather deaf. In spite of these defects, it was a weakness of his in middle life to imagine himself both young and handsome. In keeping with this purely personal opinion, he dyed his hair. Unfriendly observers have related that, as his knowledge of chemistry was not so intimate as that of physics, the colour turned out to be purple. Sir John at times could deal with a very substantial meal, for it is recorded that in some sort of dietetic contest, he ate two pounds of almonds and raisins at the close of dinner. Another of Sir John's failings was distrust of the medical profession, so that he succumbed to the results of a neglected chill brought on by a severe wetting and complicated by erysipelas on November 3, 1832.

A caricature of Leslie is to be found in the well-known "Kay's Portraits"; and a copy of the bust by S. Joseph has been placed in the National Portrait Gallery at Edinburgh.

Statistical Methods in Industry

THE conception of the ordinary business man, whether in England or the United States, of the function of statistics in industry is generally a vague one. To many the word means no more than lists of figures open to various interpretations, while few have realised that the essential element lies not in the figures but in the science of their analysis. Marketing, costing, advertising, adjusting output to anticipate fluctuations in prices and demand, and recently studies in industrial psychology, have become recognised fields for the statistician. But the link between the methods of statistical analysis and the problems of the engineer, that is to say, of the man who is concerned with the efficiency of methods of production and the quality of the thing produced, has up to the present been very little realised.

Yet when dealing with mass-production industry, the scientific method of investigation is essentially the statistical method. For whether the manufacturer is concerned with the diameter of a shaft, the strength of cotton thread or the resistance of electrical equipment, he cannot succeed in producing exactly the same article again and again; and any attempt to analyse this variation in order to locate and if possible remove some of its causes, must be based on statistical technique.

Dr. W. A. Shewhart, of the Bell Telephone Laboratories, who visited London in May to give three lectures at University College on the "Rôle of Statistical Theory in Industrial Standardization", is chairman of a committee on the development of statistical applications in engineering and manufacturing, sponsored jointly by the American Society of Mechanical Engineers and the American Society for Testing Materials. He has been largely responsible for the development of this work in the United States, and his presence in England provided just the opportunity that was needed to bring together men in different fields who had begun to realise the importance of this work in England. An immediate development resulted when the British Standards Institution called to a round table conference representatives from several engineering groups, societies and research institutes. At this meeting a small committee was appointed under the chairmanship of Mr. B. H. Wilsdon, of the Department of Scientific and Industrial Research, Building Research Station, to investigate the whole problem from the point of view of standardisation and specification. This Committee is preparing a report which will include a pamphlet intended to serve as an introduction to the subject for manufacturers and others faced with these problems. Similar action, it is understood, has been taken in Germany by the Deutscher Normenausschuss.

It is true, of course, that for a number of years individual firms have here and there made use of statistical theory in laying out efficient research programmes to improve the quality of production, or to establish sampling plans to reduce the cost of inspection; but there has been little contact between those interested on these lines. The practical worker has not fully realised the potentiality of the statistical tool, nor has he had any opportunity of discovering how similar problems have been dealt with in the research institutes or factories of other firms in the same field or in other industries. At the same time, the mathematical statistician has not understood the lines along which theory could be developed most helpfully.

Recently in Great Britain Dr. Egon S. Pearson, of the Department of Applied Statistics at University College, London, has taken a leading part in an attempt to bring together those different interests. Dr. Pearson has not only made important contributions to the theory involved in this new field of practical statistics, but also has had the advantage of making a close study of its application to large-scale American engineering problems; while at the York Meeting of the British Association he contributed a paper on statistical methods in the quality-control of output, which attracted a considerable amount of attention.

The Biometric Laboratory at University College, with its position in London and its long tradition as a workshop of statistical tools, would appear to be admirably placed as a centre for the development of education and research in this particular field.

Obituary

PROF. KARL, RITTER VON GOEBEL, For. Mem. R.S.

THE death occurred on October 9 of Geheimrat Prof. Karl, Ritter von Goebel, professor of botany in the University of Munich, president of the Bavarian Academy of Sciences, and foreign member of the Royal Societies of London and Edinburgh, the Linnæan Society, and leading academies of Europe and America. Von Goebel was without question the most prominent exponent of plant morphology of his time.

Two extreme aspects of biological science may be distinguished, and they are often pursued with but slight relation one to the other: namely, the morphological, which concentrates upon the form of the object studied, and the physiological, which concentrates on function. But neither of these can attain full success without the other. The best results will follow from some middle position. This is the key to the botanical work of von Goebel's life, as it was also to that of his great master, Hofmeister. Neither of these was a plant morphologist in the narrower sense of the formalist. Both tried to arrive at a knowledge of form through experimental study of the living plant. Both pursued organography, being impelled to fathom the problem: How does conformation come to be? The morphology of the present day is no longer formal and idealistic, but organographic. The change was due in the first instance to Hofmeister, Sachs, and Herbert Spencer; as von Goebel himself remarks in the preface to the first edition of his "Organographie", dated 1897. A general presentation of this newer aspect of the morphology of plants within the pages of a single book has been the work of von Goebel himself. The completion of the third and greatly extended edition of his treatise has almost coincided with its author's death.

This event may be held as closing a brilliant chapter in the history of botanical science. The period which it covers opened in 1847, when Hofmeister, by profession a bookseller and publisher in Leipzig, completed his comparative studies on mosses and ferns, and made his results public. He first brought to light the fact that a common life-history underlies the development of them all, with regularly alternating generations, one sexual the other neutral. He later extended his synthesis to include coniferous trees, thus drawing together seed-plants, ferns, and mosses into a common scheme.

Soon after the publication of these wonderful studies, Hofmeister was appointed directly from his place of business to the chair of botany in the University of Heidelberg, and afterwards went to Tübingen. Such happenings were without parallel in the rigid academic system of the time in Germany. Among the latest of the pupils of Hofmeister in Tübingen was young Goebel, who thus received at first-hand the stimulus of the greatest master of his time in plant morphology. Afterwards he became assistant to Sachs in Würzburg, and to de Bary in Strassburg: from both of these he derived experience and skill in physiological and cultural methods. Thus equipped, by education of a mind prone to quick perception and of unusual penetrating power, Goebel soon made his mark in research, and received academic promotion. His first chair was in Rostock: after a brief tenure he was posted thence to Marburg, and in 1891 he was finally appointed to the University of Munich, where he remained for life.

Von Goebel's contributions to botanical literature were extensive and varied. A complete list of them up to 1924 was included in the "Festschrift", published in 1925 in celebration of his seventieth birthday, as a double volume of *Flora*, a journal which he himself had edited since 1889. His writings range in time from 1877 to the day of his death, relating chiefly to bryophytes and vascular plants. They are based upon his own observations and collections, made during his extensive journeys to both eastern and western tropics, and particularly to Java, and the Buitenzorg garden. They deal not only with material collected in the open, but also include the results of his cultures within the Munich garden, over which he had official control. His experiments, summarised in his "Experimentelle Morphologie der Pflanzen" (Leipzig, 1908), were directed mainly towards a knowledge of causality, and particularly to the elucidation of the effect of environment upon symmetry. Such inquiries he seemed to prefer above those leading directly towards phyletic conclusions. Indeed he always appeared to feel some mistrust of phyletic argument, and to prefer to search deeper into the causality of those features which are too often used as mere counters in facile comparison by students of descent. In this preference he will always have the sympathy of those interested in phylogeny who wish for sound conclusions rather than immediate results.

In 1924 von Goebel published a volume in celebration of the centenary of the birth of his master, Hofmeister. A translation was published in 1925 by the Ray Society (vol. 111), and reviewed in NATURE for October 2, 1926. Nothing that he ever wrote is more self-revealing than this small book. The former student, himself a professor of more than forty years standing, who had travelled in all quarters of the world, and possessed an exceptional knowledge of plants whether growing in the open or as subjects of experiment, gives a truly philosophical analysis of his teacher's work in the light of a later generation. The book is not a mere appreciation, but a critical review. The author does not hesitate to expose points where Hofmeister's earlier position does not accord with later aspects of the science. As remarked by the reviewer in NATURE, this feature, associated with an unusually penetrating mind, makes von

Goebel's volume a most valuable addition to philosophical botany.

The production of von Goebel's "Organographie der Pflanzen", with its three progressive editions, has been a very great achievement. So large a book is in danger of suffering from the wealth of its material. When a work runs to more than 2,000 large pages, with above 2,000 illustrations, there is a risk of its becoming encyclopædic, and of its use being as a book of reference rather than a work to be read directly through. This may be but a confession of weakness in the user. As a summation of the living morphology of the time, critically stated, von Goebel's "Organography" stands unrivalled, whether as the achievement of a single brain, or as an epitome of the work of a long life of intense activity, and of unusual opportunity. Nothing like it has appeared before in the literature of botany.

Von Goebel has been a *persona grata* in his frequent visits to Great Britain. This was due partly to his own personality, partly to the character of his work, and partly it was a consequence of his command of the English language. His first introduction to British readers as a body was through his revision of the systematic section of Sachs's textbook, the translation of which was published by the Oxford University Press, under the title of "Outlines of Classification and Special Morphology of Plants" (1887). This was followed by the translation of the first edition of his "Organographie der Pflanzen" (1900–1905), both being edited by Sir Isaac Bayley Balfour. These books readily reached the hands of advanced British students: but for those engaged in morphological research von Goebel's more special writings have been for more than half a century indispensable: not only have they provided a wealth of new facts, but they have also been more influential than those of any other current writer in shaping the course of morphological inquiry.

Prof. von Goebel was born in 1855, at Billighem in Baden. He was tall and robust in figure, but with a face that suggested gentleness of character, combined with a dreamy expression of the eyes. He was, however, firm in his opinions, and resolute in their support. Nevertheless his manner in controversy was restrained, and tinged sometimes with humour. This came out particularly in his use of well-chosen classical quotations, applied so as to soften the otherwise keen point of an argument. He leaves behind the memory of a gracious personality, to whom the science of botany owes a supreme debt not only as a great observer, but also as a safe guide to correct channels of thought. F. O. B.

MR. A. CHASTON CHAPMAN, F.R.S.

CHEMISTRY sustained a severe loss in the death on October 17, at sixty-three years of age, of Alfred Chaston Chapman, one of the remaining chemists of a type that is disappearing. A consulting chemist and public analyst with a large and important practice, up to the last he was indefatigable in the pursuit of his scientific studies, and this in spite of the many calls on his time arising from the public duties and the many voluntary services he undertook.

Chapman received his training in chemistry at University College under Williamson, and remained in close touch with that College when Ramsay succeeded as professor. While quite young he started for himself as a consulting chemist, specialising in the fermentation industries, and soon acquired a position which was enhanced by his published work. An excellent organic chemist, he investigated the constituents of the essential oil of hops, some of them in great detail, such as humulene, and applied the same methods to the identification of a new hydrocarbon (spinacene) present in large quantity in certain fish liver oils. In the domain of general analytical work he contributed many useful processes; he was alive to the application of new chemical reagents and methods, to which he devoted a lecture to the Chemical Society, and in this connexion strongly advocated setting up chairs of analytical chemistry in the universities, on account of the range of discipline and chemical experience afforded by that subject.

Equally interested in life processes—he never ceased to marvel at the "wonderful laboratory of the yeast cell"—Chapman devoted much time to mycological and bacteriological work, evolving processes which required this technique. Some of this he described in special papers and an account of his views on the industrial uses of micro-organism will be found in his Cantor Lectures before the Royal Society of Arts. These studies led him to advocate with his usual cogency the setting up of an Institute for Industrial Microbiology, in which would be carried on systematic research and training, together with the formation of a collection of pure cultures. Although this has not materialised, his advice as a member of the Chemistry Research Board of the Department of Scientific and Industrial Research was valued in connexion with a start that is being made towards the fulfilment of some of these objects. In 1920 he was elected into the Royal Society.

Many institutions sought the advantage of Chapman's sound judgment of men and things. Thus he had held the offices of president of the Institute of Chemistry, of the Society of Public Analysts, of the Royal Microscopical Society, of the Institute of Brewing, and he was vice-president and benefactor of the Royal Institution. Of his assistance to Governmental committees, examples are his membership of the Royal Commission of Awards to Inventors, the scientific panel of the Board of Trade, Advisory Committee of the Imperial Institute, and the Forest Products and Chemistry Research Boards of the Department of Scientific and Industrial Research.

Among Chapman's activities was his interest in the antiquarian side of chemistry, and he delighted

to show to his friends and describe with detailed knowledge his library of books relating to the time when the Royal Society was founded and the succeeding century.

Chaston Chapman will be remembered as a cogent writer and exponent of his views, but his friends have to lament the loss of one whose striking and dignified figure, kindly humour and uniform graciousness endeared him to so many.

ROBERT ROBERTSON.

WE regret to announce the following deaths:

Prof. Louis Duparc, professor of mineralogy and petrography, analytical chemistry and toxicology at the University of Geneva, a foreign member of the Geological Society of London, known chiefly for his work in mineralogy, on October 21, aged sixty-six years.

Dr. Barton W. Evermann, director of the Museum and the Steinhart Aquarium of the California Academy of Sciences, who has published much work on ichthyology, especially with relation to the geographical distribution of fishes, on September 27, aged seventy-eight years.

Prof. K. K. Gedroiz, director of the Experimental Station of the Scientific Institute of Fertilisers, Moscow, a well known worker in soil science, on October 5.

News and Views

Diary of Societies

ANNOUNCEMENTS of meetings of scientific societies, and lists of papers to be read, have increased so greatly in recent years that it has become necessary to reconsider the claims which such particulars may reasonably make upon the space they have hitherto occupied in the "Diary of Societies" in NATURE. From the point of view of interest, it may be doubted whether weekly lists of meetings and papers running to three columns or more merit publication. In most cases fellows of societies receive such announcements direct, and the chief advantage of including the lists in our "Diary" is that fellows of other societies may see what is coming on, and may wish to attend meetings outside their own special societies. Several difficulties arise, however, even on this assumption. Meetings of scientific and technical societies are usually not open to visitors, and often a dozen or more papers may be announced in a list though only one or two papers may be actually read, the rest being read in title only.

Announcements and Reports

IF it is suggested that full lists of papers serve a useful purpose as indicating directions of scientific activity, then the question arises why such lists should be limited to London and some provincial centres. NATURE is an international organ of science, and might just as appropriately publish weekly lists of papers communicated to national scientific societies and academies outside Great Britain. Under "Societies and Academies", we record the proceedings of many such societies, giving short summaries of papers received, while our columns of "Research Items" direct attention to subjects of particular interest or importance. There is thus little justification for devoting excessive space to announcements of ordinary meetings and lists of papers, and we propose in future to include under the title of "Forthcoming Events" only special meetings, lectures, and discussions, or meetings at which single papers or topics having much the same character as that of lectures are being presented. In adopting this plan, we have in mind not only considerations of space but also the interests of the majority of the readers of NATURE abroad as well as at home; and we need scarcely add that any suggestions as to what might be usefully included or excluded from this new scheme, bearing these two points in mind, would be much appreciated.

The Shirley Institute

SOME anxiety regarding the future of the Shirley Institute was expressed at the annual meeting of the British Cotton Industry Research Association at Didsbury, Manchester, held on October 19. These misgivings were not about the ability of the Institute to continue to carry out fruitful investigations but about the necessary financial support. The Institute has a staff of two hundred, more than sixty of whom are university graduates, and Dr. R. H. Pickard expressed the opinion that the Institute could usefully employ at least twice as many people as at present on the investigation of scientific and technical problems to which the industry requires answers. The work on investigating current trade problems has grown to such an extent as to crowd out much of the fundamental research, and only one sixth of the work is now the long distance research upon which the future of the Association and the industry so largely depends. Financial arrangements made in connexion with the Rayon Department terminate next June and those for the Cotton Department in June 1934. With the exhaustion of the £1,000,000 fund, Government grants to the Association will in future come by annual vote and may accordingly be still further decreased through the need for public economy. The Institute costs about £65,000 a year to run and there is a deficit on the past year of £5,600, largely owing to a corresponding reduction in the Government grant. Only about £25,000 comes from the subscriptions of the 1,200 firms who are members of the Association and these subscriptions were described by the chairman, Mr. H. P. Greg, as ridiculously out of proportion to the size and importance of the cotton industry even in times of bad trade. Contributions of £10 from a firm with a capital of £100,000 or 50,000 spindles, or of £5 from a manufacturer with 1,000 looms are unworthy of the industry or of the results obtained.

Research and the Cotton Industry

The actual results obtained in the scientific research carried out at the Shirley Institute are the property of the members subscribing and this undoubtedly handicaps the Association in propaganda work. Enough regarding the work, however, was revealed in general terms at the annual meeting to indicate the actual and potential value of the Institute to the industry. The staff has been in contact during the year with more than 90 per cent of the member firms. Results already obtained fully justify Mr. Greg's assertion that economy on research even in the days of bad trade is unwise and unprofitable, and that the Association is worthy of far more generous support by the industry. The number of problems already raised by members which cannot be attacked by the Institute is considerable and the diversion of effort from long-range or fundamental research to current trade problems is a serious threat to the future development and prosperity of the industry. These are matters in which the nation as a whole is vitally concerned, but it cannot be expected that the direct contribution of the State can be materially increased except *pari passu* with a fitting acceptance by the industry itself of its own financial responsibilities for research.

Archæological Studies in Mexico

A decision of the Supreme Court of Mexico, it is reported by Science Service (Washington, D.C.), is expected during the current month, which is of considerable moment for the future study of the archæology of Central America. The point at issue is the control by individual States of the archæological sites within their respective boundaries. For some years the Central Government, largely owing to the influence of Señor Gamio, himself an archæologist of note, has displayed commendable energy in the examination and excavation of the archæological sites of the country. Any decision which would hamper or disturb the organisation of systematic exploration would be unfortunate in the extreme. The arrangements for the season now opening are already complete; but work cannot go forward until the decision of the courts is known. It may be hoped that whatever the verdict, some *modus vivendi* will be attained to satisfy both local interests and any claims the Central Government may justly put forward on the ground of its superior facilities for organised research.

The archæological activities which are delayed pending decision are considerable. At Monte Alban, where the now famous gold treasure was discovered in a tomb this year, an appropriation three times as large as that of last year is to be expended in the further excavation of the innumerable tombs on the site; while stratigraphical study is to be carried on with a view of correlation with Maya sites to the east, south and north. The exploration of a Zapotec fortress known as Quiengola, south of Monte Alban, is to be initiated; and further explorations are to be made in the tomb at Texmelincan, the remote area of Guerrero, from which part only of the contents, including a number of gold objects, was removed at the time of its discovery early this year. In the important Toltec city of Teotihuacan, near Mexico City, the excavation of the "Avenue of the Dead", the mile-long central axis of the city with its row of mounds, now known to be the platforms of temples, is to be continued. At Chichen Itzá, which may be considered the strategic point for at least one period of Mayan history, important work on the interior of the pyramid of the Temple of Kukulkan, the Bird Snake, will be carried further. This pyramid, 90 ft. high, is the highest in the city, and in last season's excavation was found to enclose a smaller pyramid. It is intended this year to explore this contained pyramid and search for other internal structures. This outline of impending excavation, brief as it is, will indicate the extent of the interests involved in the forthcoming decision, quite apart from any questions which may arise affecting the position of the numerous expeditions from the United States now operating in Mexico.

The Horniman Museum and Library

The late Mr. Emslie J. Horniman has bequeathed a sum of £10,000, free of duty, to the London County Council, for the purpose of providing an extension to the Horniman Museum, Forest Hill. The Museum was built by the late Mr. John E. Horniman, father of the testator, and before it was opened to the public he presented it and its contents, in 1901, to the London County Council. As is usual, and perhaps inevitable, in museums, the collections have since outgrown the accommodation, with the result that cases have become overcrowded, and progress has been hampered. This is more especially so with the collections dealing with the material culture of backward peoples. The provision of additional space will enable the present exhibited series to be opened out and extended, thus furthering that educational arrangement of the collections which has been the constant aim of the Museum authorities. It may be noted that Mr. Horniman's interest in the Museum has been shown in many ways, notably in the provision, in 1912, of an extension for the purposes of a lecture hall and library.

Under Dr. H. S. Harrison, who was appointed curator in 1904, the collections have been built up continuously with the view of the function of the Museum as providing material for the study of the development of the arts and crafts of primitive races and the natural history of man and animals. The educational value of the Museum collections has been much enhanced by the excellent series of handbooks, prepared by the staff, which deal, in a scientific spirit, but in not too technical a manner, with the developmental aspect of the collections, illustrating such topics as fire-making, transport, tools from the stone age to the steel age, and the like. The enlightened policy of the education authority for London in promoting lectures on the

Museum collections and related subjects, which teachers are encouraged to attend, has given the Horniman Museum a unique place among the educational facilities of London.

The Royal College of Physicians and Preventive Medicine

IN his Harveian oration delivered before the Royal College of Physicians of London on October 18, Sir George Newman, chief medical officer of the Ministry of Health, discussed the debt of preventive medicine to Harvey and the College. He showed first of all that Harvey's discovery of the circulation of the blood led directly to the conception of physiological balance elaborated by Claude Bernard, who formulated the synthetic principle that all the vital functions of the body establish jointly a constant and stable internal environment for the organism living in a variable external environment. Subsequent discoveries proved that physical health and mental capacity depend upon a mutual contribution of nutrition, hormones, nervous regulation and oxygenation of the circulating blood, and that these factors act in the prevention of disease. The application of the Harveian method and spirit to the study of the cause and control of infective disease and artificial immunity was then considered. Sir George maintained that throughout its history the Royal College of Physicians, with which Harvey was so closely connected, has been the foster-mother of sound medical practice and has cultivated the Renaissance spirit of true learning and inquiry. The preventive work of the College is illustrated by its participation in the pharmacopoeias published between 1618 and 1851, after which year this duty was transferred to the General Medical Council by the Medical Act of 1858; its recommendations drawn up in 1720 for the prevention of plague; its petition to Parliament in 1725 which led to the suppression of gin shops and the restriction of private retail sales; its constant advocacy of vaccination; the introduction of registration of the causes of death and the nomenclature of disease in 1837; and the creation in conjunction with the Royal College of Surgeons of a diploma of public health and afterwards of a similar diploma in tropical medicine and hygiene. In conclusion, Sir George dealt with the development of a communal medical service and emphasised the necessity of mutual co-ordination between all channels and means of medical activity.

Chaucer and Contemporary Medicine

AT a meeting of the Osler Club on October 21, Dr. J. D. Rolleston read a paper on "Chaucer and Medieval Medicine", which he commenced by a quotation from the modern version of some of the "Canterbury Tales" published in 1700 by Dryden, who after describing Chaucer as the father of English poetry continues: "He is a perpetual fountain of good sense, learned in all sciences and therefore speaks properly on all subjects. . . . Chaucer followed Nature everywhere, but was never so bold as to go beyond her." Although a few references to Chaucer are to be found in the works of some British medical historians, no essay dealing with the allusions to contemporary medicine in his works has hitherto been published, if one may judge from the absence of any entry in the Surgeon-General's Catalogue relating to Chaucer, in striking contrast with medical articles on Shakespeare or Goethe or even Dante and Byron. Dr. Rolleston, however, maintained that not only in the "Canterbury Tales", including the lengthy prose discourses of Melibeus and the Parson, as well as in Troilus and Criseyde, but also in many of the minor poems, there is much to interest the medical reader as well as delight the literary student. After a brief sketch of Chaucer's life, during which the poet became acquainted with all ranks of society, including men of science and learning, Dr. Rolleston dealt with the passages of medical interest in his works under the four headings, the medical profession in Chaucer's time, prevalent medical doctrines, diseases and their treatment, and miscellaneous topics.

Monument to Ernest Solvay

ON October 16 in the presence of the King of the Belgians and the Duke of Brabant, a monument was unveiled in Brussels to Ernest Solvay, the eminent chemist, philanthropist and publicist. Solvay was born at Rebecq in Brabant on April 16, 1838, and died in Brussels on May 26, 1922. The foundation of all his success in chemical industry and his immense wealth was his discovery of the ammonia-soda process. To the unfortunate Nicholas Leblanc (1753–1806), whose statue stands in front of the Conservatoire des Arts et Métiers in Paris, the world owed the first successful process for manufacturing artificial soda, and by 1863, the year in which Solvay took out his patent, the world production of soda was about 300,000 tons a year. The Solvay process, after the many initial difficulties had been overcome, proved far more economical than the Leblanc process, and by 1914 there were some twenty-three works in various parts of the world engaged in the Solvay ammonia-soda process, capable of producing about 2,000,000 tons of soda ash a year. Mr. Runciman, President of the Board of Trade, in a speech delivered on October 20, when dealing with the question of trade recovery, said that "one first-class invention is worth fifty Acts of Parliament". To that class of invention Solvay's belongs.

Trevithick Centenary

THE centenary of the death of Richard Trevithick occurs next April and steps have been taken by the Newcomen Society to commemorate Trevithick's life and work. In response to an invitation sent out by the Society, there was a large gathering of representatives of engineering institutions from many parts of Great Britain at a meeting to discuss the matter held at the Institution of Civil Engineers on October 20, and a committee was formed to deal with the commemoration as an international affair. The president-elect of the Institution of Civil Engineers is to be asked to be chairman of the committee and Mr. H. W. Dickinson, honorary secretary of the

Newcomen Society was elected secretary. The committee has been asked to consider the questions of memorial services in Westminster Abbey, where there is a window to Trevithick, and at Dartford Church, in the grounds of which he was buried; a memorial lecture; the placing of tablets at Euston, where his engine "Catch-me-who-can" ran, on the site of his birthplace and at Penydarran, South Wales. It is also proposed to publish a memorial volume containing a good account of his life and work; no such work is at present available.

The Electric Grid

Prof. E. W. Marchant gave his presidential address to the Institution of Electrical Engineers on October 20. After discussing training and research he dwelt on the importance of some of the applications of psychology which enable men most suitable for special kinds of work to be chosen. For example, in direction-finding work in the Navy, it has been found possible to pick out men who can tell with high accuracy the direction from which a sound comes. Prof. Marchant went on to speak of the electric grid in Great Britain which has been in course of construction for the last four or five years and will be completed in a few months. The original eight year programme has been cut down by two years. The next stage in the development of electricity is the trading stage. Assuming that progress proceeds as rapidly as during the development of the grid, Great Britain will soon be completely electrified. Prof. Marchant divided the supply of electricity into three stages, generation, transmission and distribution. So far as generation is concerned, the range of possible improvements is now small. Similarly, great improvements have been made in the technical design of transmission lines. It is the final stage of the problem, namely, the distribution and utilisation of electrical energy, which offers the greatest scope. To do this successfully, there must be a great demand and the public must be educated so as to be ready to take full advantage of electricity for all kinds of purposes. He mentioned that in Germany electrical laboratories have been installed at small cost by manufacturers in all schools. These are equipped with electrical apparatus so as to familiarise the children with electrical heaters, cookers, kettles, irons, etc.

Meteorological Effects during the Total Solar Eclipse

Dr. C. F. Brooks, of the U.S. Weather Bureau, has given a brief preliminary account (*Bull. Am. Meteorological Soc.*, Aug.–Sept. 1932, vol. 13, pp. 159–160) of the co-operative effort made in the United States and eastern Canada to determine the effects upon the atmosphere of the total eclipse of the sun on August 31 last. The programme of meteorological observations was determined largely by the Blue Hill Observatory of Harvard University, but the scheme was carried out with the aid of many public bodies and private individuals. Special measurements were made of the radiation from sun and sky; conditions in the upper atmosphere were measured by meteorographs carried by aeroplanes and captive balloons; numerous ordinary meteorological observations were carried out by the regular observers of the U.S. Weather Bureau and by a large number of auxiliary voluntary observers.

The large mass of observational material obtained in this way has still to be examined and discussed; Dr. Brooks mentions, however, a few interesting facts that have already come to light. He suggests that the cloudy skies that spoiled the view of the eclipse for so many and interfered with the work of the astronomers, were far from being a drawback for the meteorological work. There were clouds at five different levels in parts of New England, and these included both stratiform and cumuliform clouds. Generally speaking, the cumulus clouds, which half covered the sky locally just before the eclipse, disappeared during the eclipse, as the cutting off of the main heat supply for the surface layers of the atmosphere checked convection, but the stratiform clouds higher up in some instances developed rapidly, so as to cause the sky to become completely overcast. Upward-flowing mountain breezes generally ceased, but, doubtless owing to the short duration of the period of reduced radiation, katabatic winds did not develop. The fall of temperature near the ground varied greatly, mainly owing to the changing amount of cloud: it ranged from 2° F. to 11° F., the latter figure representing the combination of two favourable factors—absence of cloud and sandiness of the soil, with its concomitant low specific heat. The publication of the more complete discussion of the observations will be awaited with interest by meteorologists.

Elm Disease and its Distribution

For the fifth year in succession the Forestry Commissioners have had a survey made on the status of the elm disease (*Graphium ulmi*). First observed on the Continent in 1919, and in England in 1927, the disease is now common throughout western and northern Europe, and more recently its occurrence has been noted on a few trees so far away as Ohio in the United States. In England between 1927 and 1931 it increased steadily both as regards the number of outbreaks and the damaging effect on the trees. The most notable feature in this year's survey is the reduced virulence of attack in nearly every area visited. It is quite impossible to say whether this diminution is merely a temporary check in the progress of the disease or the first sign of recovery. Elm bark beetles have long been suspected as being the principal means by which the disease is spread and this has now been proved to be the case. A great deal of work has been carried out in Holland on the relative resistance to attack of the various species of elms. So far only certain Asiatic species have proved immune and for the most part these are small trees unlikely to take the place of the English elm. All kinds of elms ordinarily planted in England appear to be susceptible; but, judging from the investigations conducted in Holland, there is some foundation for the hope that completely resistant forms of the common species may yet become available.

Recent Acquisitions at the Natural History Museum

THE Entomological Department of the British Museum (Natural History) has recently acquired the collection of the economically important Thysanoptera, or thrips, formed by Dr. R. S. Bagnall, comprising more than 17,000 specimens, of which about 430 are types and 750 paratypes. Some 8000 insects of various orders, but mainly Diptera, have been collected for the Department in the High Tatra Mountains in Poland and Czechoslovakia by Miss D. Aubertin and Miss E. Trewavas. The King of the Hedjaz, Nejd, and its Dependencies has presented to the Geological Department the collection of fossils made by Mr. H. St. J. Philby on his recent remarkable journey in Central Arabia. It includes invertebrates from the Jurassic rocks of the Tuwaiq plateau and the Cretaceous rocks of the Arma plateau, near Riyadh, the Wahabi capital. From the area south of the Gulf of Bahrein, invertebrates of Miocene age, closely resembling those of contemporaneous rocks in the Persian oilfields, were obtained; while freshwater shells found in abundance at several localities in the middle of the great Rub' al Khali Desert show that rivers or lakes existed recently in that now arid region. The Government Geologist of the Anglo-Egyptian Sudan has presented a series of shells of Lower Tertiary age preserved in a remarkable kind of flint; these are the first fossils, other than a few plant remains, to be found in that territory. A large selection of material from the meteorite craters discovered in 1931 near Henbury, Central Australia, has been acquired for the Department of Minerals from the Kyancutta Museum, South Australia. This includes 172 pieces of meteoric iron with a total weight of 604 lb. The largest piece of 292 lb. was found in contact with three other masses (total weight 440 lb.) at a depth of 7 feet in the smallest of the thirteen craters. This is the only meteorite that has ever been excavated from inside a meteorite crater.

Additions to the Botanical Collections

MISS E. HOMBERSLEY has given to the Department of Botany of the Natural History Museum 882 paintings of British flowering plants by Miss Ellen Hawkins, who died in 1864. The paintings are of considerable merit and are accompanied by descriptions, written on the opposite page of the double sheet, which give interesting details and information. Miss Hawkins wrote the botanical appendix to Robertson's "Handbook to the Peak" (1854). Mr. Reginald Cory has presented the original manuscript and drawings of the "Tabular Distribution of the Vegetable Kingdom" by John Stuart, third Earl of Bute. The Department already possesses many plants purchased at the Earl of Bute's sale in 1794. Prof. John Percival has presented a set of all the known species of *Ægilops*. Prof. Percival's knowledge of this difficult genus of grasses makes the set of special value. Among the purchases there is a further set of H. J. Schlieben's Tanganyika plants and 668 Brazilian and Mexican plants collected by Y. Mexia and 248 drawings of liverworts (Jubuleæ) by Fr. Verdoorn.

Epidemic Diseases in Residential Schools

THERE has been since August a slight rise (which was anticipated) in the incidence of an epidemic disease of the nervous system named poliomyelitis (an infection which may sometimes result in 'infant paralysis'), though up to the present the cases have as a whole appeared singly and widely scattered. The Ministry of Health has, however, received certain inquiries as to the wisdom or expediency of closing residential schools in which such isolated cases may have occurred. The Ministry of Health is definitely of the opinion that the balance of advantage is in favour of not closing a residential school in which poliomyelitis has appeared. If the school be closed, any potential infectiousness of the disease is more widely distributed, and passes beyond such means of supervision and control as are furnished in a well-equipped residential school conducted on hygienic lines.

Co-operation of Scientific Societies

MANCHESTER chemical societies have initiated a form of co-operation which should prove of considerable value both to their members and to local industry generally. The Manchester and district sections of the Institute of Chemistry, the Society of Chemical Industry, the Society of Dyers and Colourists, the Oil and Colour Chemists' Association and the Institute of Rubber Industry, together with the Manchester Literary and Philosophical Society, have established a Joint Advisory Committee, consisting of the honorary secretaries (or other representative) of the societies concerned, in order that problems of mutual interest can be discussed and common plans arranged, and to provide a means whereby Manchester chemical opinion can be ascertained and expressed. The Committee has already published a card calendar of meetings, both scientific and social, of the participating societies, and a booklet which gives lists of officers as well as syllabuses and other information concerning the session's activities. The Chemical Society, not being organised in local sections, does not participate directly in the scheme, but—as is indicated in the booklet—fellows of that society may, under a co-operative arrangement, read papers on pure chemistry before the local section of the Society of Chemical Industry. Members of one society are cordially invited to attend meetings of any other society; hence by the promotion of personal contact and by the provision of facilities for discussion and joint action, Manchester chemists are effecting a consolidation of their own interests as well as providing an interesting experiment which will probably be found worthy of wider application. The Association of Secretaries of Technical Societies in Glasgow has also issued a programme of the meetings of the chemical and engineering societies in that city.

Musk Rat Menace

THE Trustees of the British Museum had under consideration at their meeting at the Natural History Museum on October 22 the serious position in the

country in relation to the musk rat menace, and particularly to the fact that now that the keeping of musk rats is prohibited except under the strictest regulations against their escape, the musk rat farmers have turned their attention to the coypu or nutria, an aquatic South American rodent. The latter animal is as large as a beaver, but has a tapering tail; it lives in burrows, and its fur is brown, soft and dense. The Trustees decided to recommend to the authorities concerned that the nutria should, like the musk rat, be scheduled as an animal the import of which is prohibited and which shall be kept only under licence.

Bartholomew Diaz off Cape Colony

MR. S. A. MUMFORD, of Tresta, Farley, Salisbury, Wilts., has written stating that the voyage of Bartholomew Diaz, when he touched the south coast of Cape Colony, is usually quoted as having taken place between August 1486 and December 1487, whereas in our "Calendar of Geographical Discovery" (NATURE, vol. 129, p. 177, Jan. 30, 1932), a note on the voyage appears under the date Feb. 3, 1488. The date given in our columns is based on a marginal note, probably by Christopher Columbus himself, on folio 13 of a copy of Pierre D'Ailly's "Imago Mundi", which fixes Diaz's return to Lisbon in the month of December 1488. The writer says he was present at Diaz's interview with the King of Portugal when the explorer's chart was shown and discussed. The "Imago Mundi" is at present in the Colombina at Seville.

Announcements

THE De Morgan medal of the London Mathematical Society, which is awarded triennially, has this year been awarded to Bertrand Russell in recognition of his mathematical work. The medal will be presented at the annual general meeting of the Society which will be held at Burlington House, Piccadilly, London, W.1, on November 10, at 5 P.M.

AT the annual statutory meeting of the Royal Society of Edinburgh held on October 24, the following Council was elected: *President:* Sir E. A. Sharpey-Schafer; *Vice-Presidents:* Prof. J. H. Ashworth; Dr. A. Logan Turner; Dr. J. B. Clark; Prof. James Ritchie; Sir Thomas Holland; The Hon. Lord Sands; *General Secretary:* Prof. R. A. Sampson; *Secretaries to Ordinary Meetings:* Prof. C. G. Darwin and Prof. F. A. E. Crew; *Treasurer:* Dr. James Watt; *Curator of Library and Museum:* Prof. D'Arcy W. Thompson; *Councillors:* Dr. Murray Macgregor; Dr. A. Crichton Mitchell; Prof. P. T. Herring; Prof. James P. Kendall; Prof. T. M. MacRobert; Prof. Godfrey H. Thomson; Dr. Malcolm Wilson; Prof. E. B. Bailey; Prof. J. C. Brash; Prof. A. J. Clark; Prof. A. G. Ogilvie; Prof. E. M. Wedderburn.

PROF. E. N. DA. C. ANDRADE will give four lectures at the Royal Institution on Tuesdays at 5.15 P.M. beginning November 1 on "Rays and Radiations". The course is an experiment in the treatment of a branch of modern physical science on the lines of the popular Christmas Lectures to juveniles, but Prof. Andrade will address himself on this occasion to the grown-ups. He will talk and show experiments on the gamma and ultra-violet radiations, X-rays, infra-red rays, and the particle radiations which have been used in the investigation of the inner structure of the atom. Prof. Lancelot Hogben will give three lectures, also on Tuesdays at 5.15 P.M., beginning November 29, on "Colour Change in Animals". The mechanism of colour change in such a well-known example as the chameleon will be discussed, and compared with that in other animals subject to colour changes, such as the frog, the salamander and certain fishes.

THE Council of the Institution of Civil Engineers has awarded the Indian Premium for the session 1931–32 to Sir Bernard D'O. Darley (Bahawalpur, Punjab), and the Webb Prize for the session to Mr. B. G. White (London) for papers read and discussed at ordinary meetings of the Institution. The following awards for the session have been made for "Selected Engineering Papers", published without discussion:—A Telford Gold Medal to Dr. J. F. Baker (Abbots Langley); Telford Premiums to Mr. William Muirhead (London), Mr. E. B. Cocks (London), Dr. James Orr (Glasgow), Dr. W. J. Walker (Johannesburg), and Mr. W. C. Ash (Vizagapatam, India); and a Crampton Prize to Mr. L. St. C. Rundlett (Rangoon, Burma). Awards have also been made for papers read at students' meetings in London, or by students before meetings of local associations, as follows:—The James Forrest Medal and a Miller Prize to Mr. D. J. Anderson (Glasgow), and Miller Prizes to Messrs. A. C. L. Browne (London), C. W. Scott (London), A. J. P. Pashler (Birmingham), W. D. McFadyean (London), Granville Berry (London), P. J. Stuckey (Cardiff), W. H. Morgan (Newcastle), R. R. W. Grigson (London), E. A. Turner (London), and Frank Breakwell (London).

APPLICATIONS are invited for the following appointments, on or before the dates mentioned:—A University lecturer and a University demonstrator in biochemistry at the University of Cambridge—The Professor, School of Biochemistry, Cambridge (Nov. 9). A junior assistant and guide-lecturer at the City of Birmingham Museum and Art Gallery—The Keeper (Nov. 11). An Armourers and Brasiers research fellow in metallurgy of the Royal Society—The Assistant Secretary, The Royal Society, Burlington House, W.1 (Nov. 14). A lecturer and tutor in hygiene in the Department of Education at the University of Bristol—The Secretary and Registrar (Nov. 19).

ERRATUM.—Letter on "Possible Existence of Multiply Charged Particles of Mass One" by Dr. M. Delbrück in NATURE for October 22: p. 627, col. 1, line 33, for "an α-particle is stable . . ." read "a particle in the α-particle is stable. . . ."

Letters to the Editor

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, nor to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

Bast-Sap in Plants

IN 1858 Th. Hartig directed attention to the fact that many trees yield drops of sap when their bark is punctured in summer and autumn. This sap issuing from the inner layers of the bast was said to include small quantities of nitrogenous substances with large quantities of various kinds of sugar. Obviously its motion and constitution might yield some information on the transport problem of organic substances. We found the most abundant flow when the puncture reaches the inner layers of the bast; deepening the puncture so as to reach the wood, causes the sap exuded to be instantly drawn in by the tensile water in the vessels. Hence the exuded sap is not driven out by root-pressure through the outer xylem. The exuding sap is transmitted by the sieve-tubes as we demonstrated by forcing a solution of potassium ferrocyanide into the puncture and afterwards tracing its path by means of ferric chloride.

In a stem of a young specimen of *Fraxinus excelsior* about 12 cm. in diameter all the seven or eight layers of soft bast transmitted the solution to some extent, while the inner layers transmitted it most readily. A pressure of 3 atm. drove the solution 3·5 cm. in 30 min. We have observed the flow of bast-sap in forty to fifty species of trees and in several herbaceous forms during June, July, August and September. All specimens of the same species in the same locality do not exude bast-sap simultaneously. The amounts exuded are variable. In active specimens the flow from a slit 1 mm. long continues for 30–45 min. and yields 0·1–0·2 c.c. Active flow from one puncture inhibits or reduces the flow from closely neighbouring punctures, and the amounts delivered from similar punctures at the same level, even when not influenced by neighbouring punctures, are not uniform.

Small quantities of proteins and glucose associated with considerable amounts of sucrose were found in the sap; the presence of tannin, an oxidase and a chromogen is also indicated. The sap is extruded by the turgor of a closed system in the bast (probably the sieve-tubes), and the flow only ceases when that pressure becomes negligible. Freezing point determinations give a measure of this pressure. Unexpectedly high pressures were observed ranging from 13 to 35 atm. The forces moving the sap through the bast and forcing it through the punctures are very high. Very different pressures have been observed in the same specimen on different occasions; but so far, it has always been found that the osmotic pressure of sap issuing from a higher level is greater than that coming from a lower one. Osmotic pressure gradients of 2·2–8·9 atm. per metre have been observed in the bast of *Fraxinus excelsior*.

Lateral motion is inconsiderable compared to longitudinal movement, hence from the amount exuded through a puncture of known size under the pressures available we obtain some idea of the ease with which the sap moves longitudinally in the bast. The gradient of pressure is presumably maintained by the production of carbohydrates in the leaves and their removal by condensation into products of growth (activity of the cambium) and materials of storage (sucrose, starch, etc., deposited in the bast-parenchyma, starch-sheath, cortex and medullary rays).

The difference in osmotic pressure above and below in the intact plant is available for forcing the solvent, water, of the less concentrated solutions below into the wood, thus creating a mass-movement of the solution downwards through the bast. These and other observations seem to us to support Münch's theory of mass-movement of organic substances in the bast, and probably bring into line the results of Mason's and Maskell's investigations.

Stability of the Liquid Carbon Dioxide in the Ocean

IN NATURE of July 2, p. 26, Dr. Wattenborg of Berlin presented some objections to my paper "On the Field of Stability of Liquid Carbon Dioxide in the Biosphere".[1]

It is a pity that Dr. Wattenberg in formulating his criticism used, apparently, only the short notice of my paper which recently appeared in NATURE[2] and not the paper itself. Had he read my original paper he would have saved himself from misunderstanding of my point of view.

The water of the ocean, like the water of all the deep continental water-basins, is heterogeneous as to its baric properties, presenting a substance which cannot be reproduced by experiment since it has the proportios of a specifically planetary phenomenon. In the ocean the water itself is subjected to pressures which can exceed 1000 atm./cm.[2] and at the same time the dissolved gases in the same water (which are in *an innate connexion with the troposphere*) are subjected to pressures which can not exceed 1–2 atm./cm.[2] In the thermodynamical conditions of the ocean's water all the carbon dioxide masses which are isolated (completely or partly) from the troposphere (that is, from the gases dissolved in the oceanic water), must exist in a special state of phases:

$$\text{liquid } CO_2 \rightleftarrows \text{gaseous } CO_2,$$

because the temperatures and the pressure of sea-water remain mostly below the critical point and above the critical pressure of carbon dioxide.

Marine organisms must have accommodated themselves throughout geological time to the specific state of carbon dioxide in the ocean. They have to obtain a special organisation in this respect.

I have indicated in my paper the following three examples among many of such accommodations:

1. The accommodation of plankton organisms in connexion with the low confines of their habitation.
2. The oxygen glands of deep-sea fishes in connexion with their respiration.
3. The conditions of life of micro-organisms in the bottom sediments of the ocean. The chemical processes in such sediments are regulated by micro-organisms. They are subject to changes under the influence of liquid carbonic dioxide, the possibility of existence of which in living environments cannot be denied.

The same peculiarities of carbon dioxide must influence many inorganic processes such as exhalations of gaseous carbonic dioxide in the gaseous and mineral springs on the sea-bottom.

The peculiar character of carbon dioxide in the ocean in comparison with its behaviour on the earth's surface must be taken into consideration in all conclusions concerning the state of the gaseous solutions in the ocean. There certainly must exist a lower limit than the gaseous solution of carbon dioxide in sea-water and therefore we must expect to find at greater depths only ions or hydrates of carbonic acids.

For further discussion on this subject reference must be made to my paper already cited. I have also discussed the subject in my lecture "Oceanography and Geochemistry" delivered in the Mineralogical Institute at Göttingen, which is to be published in the *Tschermaks Mineralog. u. Petrografphische Mitteilungen*.

Further study in the same field of research has been made by Prof. V. Chlopin, who has published his results in the *Comptes Rendus* of the Academy of Sciences, Leningrad, mentioned before. Prof. V. G. Chlopin has shown that in the same conditions, which have been demonstrated by me for carbon dioxide in sea-water, the inert gases (argon, krypton, xenon) must give hydrates, which are soluble in sea-water. Apparently the geochemistry of the inert gases offers here a new and promising ground for research.

Bead-Corona on Radio Antenna

DURING the period February-March 1932, of exceptionally dry atmospheric conditions, a curious high frequency - high tension - phenomenon was observed on several days on the antenna of the Hilversum (Holland) broadcasting station (λ = about 300 m., aerial power 15-20 kw.).

The aerial consists of five horizontal wires, strung between two metal masts sixty metres in height, and is connected at both sides to insulators fastened to two spreaders. There are five downleads, connected to the central part of the aerial wires.

On February 14, at 20.00, a corona was observed on the antenna, and this corona caused an acoustical effect such that the modulation of the emission could clearly be heard up to a distance of approximately 800 m. A reduction of the antenna power from 20 kw. to 12 kw. caused the phenomenon to disappear.

Again, on March 7, at 17.00, when the antenna power was raised from 7 kw. to 20 kw., the corona on the antenna reappeared. It consisted of slowly moving luminous spheres of about 10 cm. diameter. They first appeared at one end of an outer wire, they slowly moved, following the wires towards the downleads and disappeared at a distance of about 15 m. from their origin. Several of these luminous spheres were observed to occur simultaneously with a mutual distance of 0·5 m., so that the phenomenon made the impression of a string of beads, moving towards the centre with a speed of the order of 1 m./sec.

The phenomenon usually started at an outer wire, and when this was covered with beads over a length of about 15 m., also the second, the third and the fourth wire gradually developed the beads in a similar way. The colour of the beads varied from yellow to a light blue and pink. The sound emitted by this corona (corresponding to the modulation of the transmitter) was very distinct and could be heard up to a distance of 1–1·5 kilometres, so that a big crowd gathered round the gate of the station, listening in astonishment to the voice of a preacher, directly from the heavens.

The modulation was also plainly visible in the glittering of the emitted light. On that day again the phenomenon disappeared with the reduction of the antenna power from 20 kw. to about 10 kw. At 19.00 an increase of the aerial power caused the corona to reappear.

The same phenomenon was again observed on March 9, 10, 11, 12, and 13. Since March 16 the corona has not occurred.

Influence of Impurities on the Transformation Point of Liquid Allotropic Modifications

RECENT investigations dealing with the properties of liquid nitrobenzene, in the neighbourhood of the melting point, are yielding discordant results. Wolfke and Mazur,[1] in a carefully purified specimen, observe discontinuities at 9·5° C.; this temperature, they suggest, represents the transformation point of two distinct modifications of liquid nitrobenzene. Stewart,[2] using X-rays, confirms the assumption. Massy, Warren, and Wolfenden,[3] Newton Friend,[4] and Piekara [5] were unable to discover any discontinuities. The interesting question arises as to how far these discrepancies may be accounted for by assuming slight impurities to have been present in the samples used.

When two diluted solution phases co-exist, we have the well-known equation

$$\frac{L}{\vartheta}d\vartheta = \frac{x_2 - x_1}{x_1}R\vartheta dx_1$$

where L stands for the heat of transformation from phase (1) to phase (2), R is the gas constant (both per gm. mol.), x_1 and x_2 are the molecular concentrations in phases (1) and (2), and ϑ denotes the absolute temperature of transformation (see, for example, Van der Waals' "Lehrbuch der Thermodynamik", vol. 2, p. 80); the pressure is here assumed to remain constant. For the difference $\Delta\vartheta$ of the transformation points of the pure substance and that of the solution, we accordingly obtain

$$\Delta\vartheta = \frac{d\vartheta}{dx_1}x_1 = \frac{R\vartheta^2}{L}(x_2 - x_1).$$

That the allotropic modifications have unequal dissolving power is a common occurrence; the dielectric constant, which influences the dissolving power, increases nearly fourfold when we pass from nitrobenzene II to nitrobenzene I; thus x_1 and x_2 may be assumed unequal. Since the heat of transformation L for nitrobenzene ((1) $\longrightarrow$ (2)) is exceptionally small (0·14 cal. per gm.), the effect of slight impurities may be to depress the transformation point below the freezing point; the liquid phase, nitrobenzene II, permanent below 9·5° C., would then disappear.

If μ denotes the integral molecular concentration of the solution and α the ratio x_2/x_1, then the term $x_2 - x_1$ varies, during the transformation (1) $\longrightarrow$ (2), from the value $\mu(\alpha - 1)$ to $\mu\left(1 - \frac{1}{\alpha}\right)$. The phase (2) appears at the temperature

$$\vartheta + \frac{R\vartheta^2}{L}\mu(\alpha - 1);$$

the phase (1), however, does not disappear entirely until the temperature

$$\vartheta + \frac{R\vartheta^2}{L}\mu\left(1 - \frac{1}{\alpha}\right)$$

is reached. In the case of nitrobenzene we may probably admit that $\alpha < 1$.

In Fig. 1 are shown the probable coexistence lines

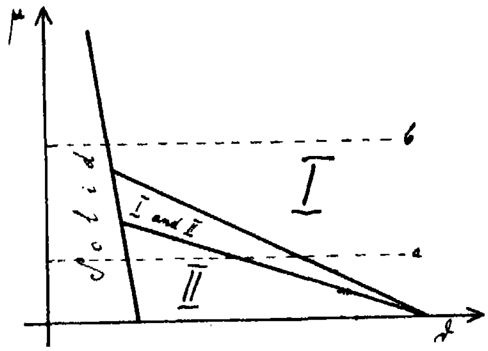

FIG. 1.

of the various phases of nitrobenzene. The dotted line a corresponds to Mazur's numerical data, the line b expresses results which would be found with samples of a less degree of purity.

Proof of Stability of Poiseuille's Flow

IN some recent papers[1] it is shown that there exists an absolute analogy concerning the question of stability of

(1*a*) disturbances being symmetric about the axis, of P.'s flow (= steady flow through a straight pipe of uniform circular section).	(1*b*) two dimensional disturbances of the steady flow between two parallel planes, the velocity being a linear function of the distance y from the axis.
(2*a*) three dimensional disturbances of P.'s flow.	(2*b*) two dimensional disturbances of the steady flow between two parallel planes, the velocity being a parabolic function of the distance y from the axis.

It was, therefore, concluded that the investigation of (2*b*) would elucidate also the question of stability of (2*a*). To make the investigation of (2*b*) possible, the problem was divided into four parts according to the following scheme:

(1) α small αR large	(2) α large αR large
(3) α small αR small	(4) α large αR small

$\alpha = 2\pi/\lambda$ being determined by the wave-length, λ, of the disturbance (R = Reynolds's number). Since in the limit of vanishing viscosity (that is, $\alpha R \to \infty$) there exists the solution $\alpha = c = \theta$, $\psi = 1 - y^2$, which can be regarded as representing a degenerate oscillation of the undisturbed flow, the most important case will be α small, αR large.

It was possible to integrate the problem approximately by dividing the stream function ψ into an even and an odd part, by reducing the differential equation of the fourth order to a differential equation of the second order and by complex (Laplace) integration of the latter equation, expanding asymptotically the particular solutions, parameter and argument both being large. The even part gives the following transcendental equation for c = β/α : $e^{(1+i)z} = i$, z being $\left[\sqrt{c} - (1-c)\, ln \frac{1+\sqrt{c}}{\sqrt{1-c}}\right]\sqrt{\frac{\alpha R}{2}}$, that is, when c is small, $z = \frac{1}{3} c^{3/2} (2\alpha R)^{1/2}$.

The roots are in this limit

$$c = \left[\frac{3\pi}{2}\left(2n + \frac{1}{2}\right)\right]^{2/3} \Big/ (\alpha R)^{1/3} \cdot \frac{\sqrt{3} + i}{2}.$$

Since something similar is true for the odd part and also for α large, αR large, the absolute stability of Poiseuille's flow is established.

The detailed proofs and a discussion of the streamlines of the disturbed motion will be given in a paper to appear in the *Ann. d. Phys.*

Science Teaching in Schools

IN his letter to NATURE of October 1 Mr. Shearcroft accepts the gloomy picture of the state of science teaching in schools with which we are becoming familiar. He writes as a teacher of science, but there are many other teachers of science who will not agree with him. Writing with the authority of the Committee of the Science Masters' Association I wish to put on record our opinion, shared we are certain by most of our members, that the science teaching in the schools of to-day is making an important and valuable contribution to the educational development of our young people and is helping them towards an understanding of their future surroundings which they would not obtain without it. We make no extravagant claims, but we do claim that we are giving those who leave the schools some insight into the method of separating the important from the unimportant, the true from the false, and we ask for a more just appreciation of the contribution of the science teacher to the intellectual make-up of the pupils in the schools.

The Science Masters' Association exists for the advancement of science teaching in schools and

endeavours to deal with the situation as it exists. Is it not futile to talk of the "curse of useless external examinations" so long as employers ask for a definite proof that a pupil leaving school and seeking a post has shown some capability of achievement? The example of an apparent encouragement of a narrow specialisation in physics quoted by Mr. Shearcroft unfortunately exists, and the Association is emphatically opposed to the possibility of a pass in physics on an examination of this restricted nature. But it is fair to point out that of the eight examining bodies, three only accept this inadequate section of 'Sound, Light and Heat', and two of these offer alternatives which give scope for a wider treatment of the subject. Moreover, it does not necessarily follow that because pupils may be examined in 'Sound, Light and Heat' therefore schools are unable to include a fuller treatment of physics in their curriculum; nor need a teacher feel his work is under a curse because only a part of it is examined.

The widening of examination syllabuses is continually taking place and much is being done to bring together the school teacher and the university teacher for the discussion of the problems arising out of these syllabuses. Each examining body has a method by which teachers are able to make their views known, and the tendency is all in the direction of fitting the examinations to the work of the schools and so of preserving to the teachers a free hand in the development of their subjects. The professional associations, the interests of which are not confined to economics, are closely identified with these consultations, and the Science Masters' Association is very frequently consulted on both general and more detailed questions relating to science. The Board of Education's Secondary Schools Examination Council, containing representatives of the universities, teachers and education authorities, reviews all the examinations periodically.

The Science Masters' Association is anxious for progress—witness the enthusiastic reception given to the address of our president, Dr. C. Norwood, at the annual meeting in January last—and will welcome any practical projects for the furtherance of its objects. Both teachers and examining bodies may be assumed to be actively interested in the welfare of the pupils in the schools, and, whilst purely destructive criticism of their work is easy, it is not usually very helpful.

T. HARTLEY,
(Chairman, Science Masters' Association).

Pelagic Animals off the South-West Coasts of the British Isles

THE occurrence of the skeleton of the floating siphonophore *Velella spirans* on our south-western shores is of common occurrence. But it is only occasionally that the living animal is driven ashore in large numbers. Although this is probably largely a wind effect it is of interest to put these invasions on record for future reference, for its presence may be an indication either of wind drift of surface water or of increased inflow of Atlantic water; in either of these circumstances it is desirable to know what other plankton animals showed unusual abundance.

Of previous records we have in the Plymouth Marine Fauna, March and October, 1903, at Looe; Jan., 1916, at Plymouth and on Cornish coast; and Jan., 1921, at Bude; and in NATURE for July 26, 1924, there is a record by Herdman of its occurrence at Port Erin. One of us also remembers its occurrence in large quantities at Newquay in January, 1922, which was probably due to prevalent southerly winds.

This summer *Velella* has again arrived in large numbers. In the second week in September large specimens were being washed up on the Fistral Beach at Newquay, Cornwall, and their presence was recorded about the same time at Padstow.

In the south-west of Ireland great numbers of fresh specimens were seen in August on the Kerry shores of the Kenmare estuary and with them were found shells of the pelagic mollusc, *Ianthina*, with the soft parts decomposing. Miss M. Delap informs us that in Valentia Harbour enormous swarms of *Velella* have been seen this year. *Ianthina* has been plentiful and lepadid barnacles of several species, attached to feathers, ashes and other floating objects, have been washed ashore.

This year also the pelagic tunicate *Salpa fusiformis* was being caught in numbers in the waters of the English Channel off Plymouth during September; this is a species the occurrence of which in these waters is spasmodic and which appears in quantities at intervals only of several years.

Bacterial Enzymes in the Purification of Sewage

FROM experiments carried out at the London School of Hygiene and Tropical Medicine, in connexion with the programme of the Water Pollution Research Board of the Department of Scientific and Industrial Research, we have come to the conclusion that the purification of sewage is essentially a matter of bacterial enzymes—whether associated with living or dead bacterial cells appears to be immaterial—and mainly of oxidation-reduction enzymes. Although not excluding from some part in the process such agencies as colloidal flocculation, sedimentation and adsorption, or ruling out the possibility of some step in the purification being due to the agency of other enzymes such as proteases, lipases and carbohydrases, we nevertheless believe that the essential step in the purification of sewage is due to the agency of the bacterial oxidation-reduction enzymes.

We have shown that the uptake of oxygen by crude sewage will not take place if the latter be first sterilised by heat or by filtration, provided that sterility is maintained throughout the period of test. If, however, a small seeding of crude sewage or a small inoculum of certain bacteria be introduced into the sterile sewage a rapid uptake of oxygen results. If the seeding be first boiled no oxygen uptake follows. Certain other bacteria do not bring about the absorption of oxygen when introduced into sterile crude sewage in small numbers but if large concentrations of these organisms, washed free from contaminating media, be introduced vigorous oxygen uptake results, although the organisms do not appear to multiply. The necessary controls give negative results. That bacterial enzymes can effect the absorption of oxygen in the presence of crude sewage independently of the growth of the organism can

be shown by treating a suspension of washed *Pseudomonas fluorescens* cells with formaldehyde so that the suspension is sterile whilst its indophenol oxidase and the dehydrogenases remain active. If such a suspension be introduced into sterile sewage, uptake of oxygen results although no living bacterium can be demonstrated to be present at any time throughout the experiment.

We have further shown that sewage sludge (whether this be taken from the sedimentation tank or the humus tank) or activated sludge is enzymatically active, possessing both oxidases and dehydrogenases. Crude sewage itself, even when sterilised, acts as a substrate for the sludge dehydrogenases, whereas a good sewage effluent acts in the reverse manner, namely, as a hydrogen acceptor in the presence of the sludge and under suitable conditions. That the oxidase appears to be important is supported by the fact that the purification of crude sewage in the presence of activated sludge is inhibited by the presence of $M/1000$ potassium cyanide even when vigorous aeration proceeds. Experiments with five per cent urethane, which similarly inhibits purification of sewage on aeration with sludge, tend to support the contention that dehydrogenases play a part in sewage purification. Purification, as judged by nitrite or nitrate production, is not effected by agitating crude sewage with activated sludge in the absence of air or when the sewage is aerated with air in the presence of boiled sludge.

It is proposed shortly to publish elsewhere some of the experimental evidence in support of our tentative thesis, namely, that the most important factor in sewage purification is a series of catalysed oxidation-reduction reactions determined by bacterial enzymes, present in either living or dead bacterial cells, or liberated by them into the fluid of the reacting system.

Light as a Factor in Reproductive Periodicity

IN a letter to NATURE[1] I observed that the culture of diatoms in polarised light would be an interesting piece of research. Later, I placed a culture in a small tube in the path of light from a Nicol prism, and a similar tube using the same culture medium, in ordinary daylight: at night, light from the sky was admitted as in the day. The rate and prolificacy of reproduction were approximately the same. It appears from this that it is the length of the period of exposure, and the intensity of the light which are the chief factors; the polarisation of the light is of little importance. In this case it looks as though reproduction at night has no connexion with lunar periodicity.

To find the effect of the period of exposure to light, I then started nine culture experiments, using the same medium, and inoculated them with a pure culture of *Nitzschia paradoxa*. Three of them were exposed to day light, three to night light, and three to light from both day and night skies. These experiments were begun on August 14 and discontinued on September 1. The first quarter of the moon was on August 9, and the third quarter on August 24, so that the cultures exposed to the night sky were illuminated by a period of maximum polarisation.[2] To make the periods of exposure comparative, the day and night cultures had twelve hours each in the light, the cover which permitted access of light being changed at 8 A.M. and 8 P.M.

The results obtained were as follows:

Culture (*a*)—night light—216 hours.
Culture (*b*)—night light and day light—432 hours.
Culture (*c*)—day light—216 hours.

In cultures (*a*) no reproduction took place, no brown film spread over the bottom of the Petri dishes, and no mass of individuals could be seen with the microscope. In the cultures (*b*) reproduction occurred to the greatest extent, the brown film of diatoms spreading over the bottom of the dishes in a shorter time and in greater numbers than in either of the other two cases. In cultures (*c*) reproduction occurred, but the visible brown film appeared later, and the number of individuals was obviously less than in case (*b*), which had twice the time of exposure.

From these results it appears that the light 'ration' is very important to diatoms: moonlight alone is insufficient to stimulate reproduction, and photosynthesis must take place. The fact that food is an important factor as well as light in reproduction[3] is as true of these minute cryptogams as it is of birds and mammals.

Furthermore, it seems that polarised light promotes the hydrolysis of starch in the presence of the enzyme diastase.[4] This probably explains the asexual reproduction of diatoms at night. In the daytime photosynthesis takes place, ultra-violet light being the active component of sunlight, and starch is deposited round the pyrenoids of the cells. At night hydrolysis takes place, polarised light, in the absence of ultra-violet light, being the active component of moonlight, and this breaking down of starch is conducive to reproduction. It is quite reasonable to believe that this hydrolysis supplies the energy which stimulates the division of the nucleus.

Constitution of Cholesterol

IT is not too much to say that work published this month[1] has resolved all dubieties in regard to the main outlines of the molecular structure of the sterols and bile acids, and unquestionably the Wieland-Dane formula is correct. In addition to the change in the position of the hydroxyl group which was mentioned in my letter of October 8 a further modification of current views is necessary in order to make the pieces of the puzzle fit together. Lithobilianic acid and *iso*lithobilianic acid must be stereoisomerides and not structural isomerides as usually assumed and the seat of this persistent type of isomerism is doubtless C–8 of Wieland-Dane's formula. Thus in a *cis*-series we have lithobilianic acid, dihydrocholesterol, the Abderhalden–Diels dibasic acid; and in a *trans*-series, coprosterol and *iso*lithobilianic acid. Interchange of the isomerides

occurs when a carbonyl group is attached to positions 8 or 9 as in deoxybilianic acid and ketostadenic acid. Stereoisomerism also arises as the result of the disposition of groups round position 5.

Only a minor point of the Wieland-Dane formula remains doubtful, and that is the site chosen for the methyl group in the position common to ring II (bile acids) and ring IV. On biogenetic grounds the other point of fusion of these rings would appear to be preferable, the methyl wandering in that case into a *para*-position in certain reactions in the ergosterol series.

As a corollary to the above the paper mentioned in my earlier letter has been withdrawn.

A New Principle of Time Observation, especially for Determination of Longitude

A MAIN difficulty of accurate time determination is the personal equation of the observer. Although the term 'personal equation' suggests that any trained observer would have a fixed personality, such is not found to be the case; and two observers will differ by different amounts in varying circumstances.

Nowadays personality in time observation is to a considerable degree overcome by the 'moving wire micrometer' with which the transit instruments of observatories are generally equipped. I have heard the statement that by this means the personality of several observers is reduced to fall within 0·02 seconds of time. Experience at the Dehra Dun Observatory, where regular time observations have been in progress for the past six years by means of a transit fitted with a moving wire micrometer (hand-driven), scarcely justifies this; and I should say that the results of the several regular time observers scarcely fall within 0·04 seconds of time.

In field observations the differences are apt to be even greater, for the observer is then subjected to much greater changes of conditions than he is likely to encounter in an established observatory. For the study of the figure of the earth, longitude observations must be made at numerous field stations, and the results are apt to be marred by any personal error which is considerable and yet not constant and determinable.

Some six months ago the idea occurred to me to vary the nature of the observation, as now indicated. Instead of attempting to time the instant of a star crossing a wire in the eyepiece of a telescope by depressing a tappet and thereby making a record on a chronograph, or, with the moving wire micrometer, striving to keep the star intersected for a considerable time during which contacts cause a record on a chronograph, I proposed the following plan. The telescope is fitted with a form of shutter which is operated by the clock. This shutter obscures the star to be observed except for brief periods, controlled by the clock. The duration of the exposure should not exceed the period of persistence on the retina, say 0·07 second; and it has been found convenient to have exposures at intervals of three seconds. The eyepiece is provided with a fixed scale, appropriate to the magnification of the telescope—that on which trials have been made was divided to 0·1 mm. The observation consists in estimating the position of the star on the scale at each exposure. The star appears stationary at each exposure, and the observation is merely the reading of a scale. I cannot see that there is room for personality in the mean of a considerable number of readings well distributed over the scale. The observation is not trying to the observer.

Putting this idea into practice has offered a good many difficulties in an observatory remote from scientific supplies. Apart from the glass scale, kindly obtained for me by Sir Gerald Lenox Conyngham and sent out by air mail, I have had to contrive the other requirements from raw materials. I will not enter further into details than to say that a shutter was first placed in front of the object glass but was soon replaced by a narrow strip close to the glass scale and actuated by an electro-magnet controlled by the clock. Owing to the monsoon, clear skies have been very rare and the observations so far obtained are not sufficiently numerous to warrant final conclusions; but the results do not appear to suggest systematic error.

The application of the method to the prismatic astrolabe and to ordinary theodolites has also been considered, and seems quite feasible. As the method does not require a chronograph it offers considerable advantages for field work in difficult country where lightness of equipment is important, and if further observations confirm its precision it will also be useful for time determination in observatories.

Variations of Latitude and Great Earthquakes

THE beautiful Japanese chart of variation of latitude which accompanies Prof. Nagaoka's communication to NATURE of October 8 starts many inquiries. The motion was within six feet of swing until upset by the Mindanao earthquake, which started an annual wobble of double that amount. This may throw light on the gyroscopic causes of wobble.

Linked with this inquiry, involving the equatorial protuberance, is the uniformity of rotation. Beside checks on it by moon and planets, which can scarcely be very minute, there is the pendulum check. For that a metal pendulum cannot suffice, for the internal flow of cold metal is so slow that it takes centuries for oxidisable products to reach the surface. Only a stone pendulum can serve the question; for that a beryl cut between the axes of contraction and expansion will give a pendulum independent of temperature.

The elevation of the observing station is also involved, and partly settled by sea level. But there is no uniformity in sea level, as ocean flow will not immediately equalise rainfall and evaporation of the ocean. Suppose twenty feet of water piled up at Karachi by Indus flow; for that to equalise with the dry heat evaporation of the South Arabian Sea, it would make a slope of an inch in five miles; and, if flow varies as gradient, that would take most of a year to reach Aden. This suggests that ocean level may be twenty feet higher permanently at Karachi above Aden. It is only possible to suggest inquiry on these interlinked questions; to find solutions is a task of the future.

Research Items

Totemism among the Karadjeri.—The totemic system and social organisation of the Karadjeri tribe, which inhabits territory around Lagrange Bay, north-western Australia, is described by Mr. Ralph Piddington in *Oceania*, vol. 2, pt. 4. Although the tribe has long been under the influence of the white man, certain elements of the totemic system, such as the increase ceremonies and their associated mythology, retain the more important features of their original elements. Increase ceremonies are associated primarily with the districts in which the ceremonies are held rather than with the individual members of the totems. Not all species have their increase centres located in Karadjeri territory, but all important natural species have increase centres somewhere. There are certain prescribed forms for the ritual, though these are not so circumscribed as among the Aranda. The ceremonies are usually performed once a year only, and, if the species appears at one season only, generally just before it becomes plentiful. If the ceremony is associated with perennial foods, it may be performed at any time. Instructions to the species to become plentiful are uttered by the performers as they carry out the ritual, the districts in which it should become plentiful being named in succession. The places named are those in which the species are actually found. At many of the increase ceremonies decorations are worn, such as powdered charcoal, red ochre, white mud, white down, and blood from a human being, taken from the fore-arm by a pointed bone from a wallaby's leg, at a ceremony of which no woman should be a witness.

Ancient Hindu Temples in Burma.—The history and cult of the only Hindu temple in Burma now extant, the Nat-Hlaung temple, Pagan, is discussed by Nihar Ranjar Ray in a communication to the *Indian Antiquary* for September. It would appear that the temple was built not for housing figures of the Buddha, but for statues of deities inferior to him—Hindu figures of the different incarnations of Viṣṇu. According to tradition the temple was founded by king Taung Thugyi (A.D. 931–964); but more probably, and in accordance with another tradition, it was founded by Anaorahta, who flourished in the last half of the eleventh century, even though he was an ardent adherent of the southern Sinhalese school of Buddhism, under the influence of the Brahmanas, who were prominent at the Pagan court. The figure of the main deity of the temple once stood in a niche in a square obelisk in the centre of the interior; but after lying on the floor for long it was removed, and is now in Berlin. It was a seated image of Viṣṇu, of which the lotus throne rests on the bird Garuda posed ready to fly. The god is elaborately ornamented from head to ankles. The bird differs from other representations in Burma. It shows a short stunted human bust resting on two heavy rounded feet. A peculiar feature of the figures of the ten niches on the outer walls of the temple, is that of the seven which still remain, only four are avatars of Viṣṇu, while of the other three, one is identified as the image of Sûrya. It is of the south Indian variety. In the Vedas Sûrya is identified with the sun and is intimately related with Viṣṇu. The idea that Viṣṇu is the sun appears in the worship of the sun as Sûrya-Nârâyaṇa.

The Inheritance of Goitre.—Various hypotheses have been put forward to explain the inheritance of goitre, which is well known to be endemic in regions where the soil waters have a low iodine content but to occur sporadically elsewhere. Dr. C. B. Davenport (Carnegie Inst. Publ. No. 428) has recently made an investigation of goitrous families in a mountain valley in western Maryland. The difficulty of drawing a line, particularly in women, between functional and pathological enlargement of the thyroid, introduces some uncertainty into the results. Since many individuals in goitrous regions escape the disease while some in other areas develop it, the threshold for iodine intake and the efficiency of the thyroid must vary in different families. Dr. Davenport has compiled a number of pedigrees, and from their analysis reaches the conclusion that for the appearance of goitre two genetic factors are necessary, one dominant and sex-linked, the other dominant but not sex-linked. This hypothesis accounts for the well-known excess of females with goitre, and also for various relationships found among the offspring when one or both parents are goitrous. How widely this hypothesis is applicable can be determined by testing it with other pedigrees.

X-Ray Analysis of Teeth.—The hardness of teeth, like that of bone, is due to the deposition, in the enamel and dentine, of a salt (or salts) of calcium and phosphorus. Previous X-ray investigations have indicated the probability that these elements are deposited in the form of apatite. J. Thewlis (*Brit. J. Radiology*, **5**, 353; 1932) has recently confirmed this conclusion, in an X-ray analysis of the enamel and dentine of both human and canine teeth. The rays are more heavily absorbed by the enamel than by the dentine, due to the greater proportion of organic matter in the latter. From density determinations it appears that there is about five per cent of organic matter in the enamel but forty per cent in the dentine. The human tooth contains slightly less than the canine. It was also found that the crystallites of the dentine, in both types of teeth, are randomly oriented: the enamel crystallites, however, have one direction in common but are otherwise randomly oriented. This direction makes an angle of 20° with the normal to the tooth surface in human teeth and is coincident with the normal in canine teeth. There is a possibility that the immunity of dogs' teeth to caries may be related to the arrangement of the crystals of apatite in the enamel. Thewlis's experiments failed to disclose the presence of any other crystalline constituent.

Cytology of Spinning Glands.—St. Wajda (*Bull. Internat. Acad. Polon. Sci. et Lettres*, No. 2, Bd. II., 1931) has investigated the cytology of the spinning glands of the larvæ of the trichopterous insect *Anabolia*, and has shown that, as in the spinning glands of other insects, the nucleolar substance plays an important part in the formation of the secretion which, he states, may be produced in four different ways. (1) The nucleolar material may be extruded from the nucleus into the basal part of the cell; there it stains with acid dyes more weakly than the nucleoli, and forms a sort of pro-secretion which later

breaks up into spherules, and these lie for a long time in the cell plasma, but later increase in size at the expense of the cytoplasm and are finally passed into the lumen of the gland. (2) The nucleolar substance may be expelled from the nucleus into the cytoplasm, where it lies in large vacuoles, and from this eosinophilous material small secretion particles pass from the cytoplasm into the lumen of the gland —in this case the secretion arises directly from the nucleolus. (3) Fragmentation of the nucleolus occurs, and the pieces lie each in a vacuole and become changed by swelling and pyrenolysis into the spinning substance. (4) Pieces of chromatin change from basophile to eosinophile and become transformed into the spinning material. The nucleolar substance therefore plays the most important part in the production of the spinning secretion, as is the case in other insect larvæ previously investigated, but there is no production of the secretion in the cell plasma such as takes place in the larvæ of Myrmeleonidæ and Hymenoptera. This may be correlated with the different chemical constitution of the secretion in the Trichoptera, which 'sets' under water.

Metabolism of Potatoes affected with Leaf-Roll.—Leaf-roll of potatoes is perhaps the most serious of the so-called degeneration diseases. It has been recognised for many years that the causal virus produces an accumulation of starch in the leaves and hinders its translocation to the tuber. The cause of this hindrance forms the subject of a very extensive study by E. Barton-Wright and A. M'Bain ("Studies in the Physiology of the Virus Diseases of the Potato: A Comparison of the Carbohydrate Metabolism of Normal with that of Leaf-Roll Potatoes". *Trans. Roy. Soc. Edin.*, vol. 57, Pt. II, No. 11, 1931-32). It was found that sucrose is the sugar of translocation in healthy plants, whilst carbohydrates are removed as hexose in leaf-roll potatoes. The seasonal variation of starch content in leaf-roll tubers has also been studied, and the bearing of these factors on tuber formation is discussed. Two varieties of potato have been used for the experiments—'Arran Victory', which is not much affected by leaf-roll, and 'President', which is attacked very severely by the disease.

'Tea Yellows' in Nyasaland.—A communication from the Department of Agriculture of the Nyasaland Protectorate (Bulletin No. 3, new series) records a successful piece of work on the etiology and control of the 'yellows' disease of the tea bush, which has troubled planters in Nyasaland for many years. This work, done by Dr. H. H. Storey, of the Agricultural Research Station Amani, Tanganyika, and Mr. H. Leach, mycologist to the Nyasaland Department of Agriculture, leaves little doubt that 'tea yellows' is a deficiency disease due to lack of sulphur in the soil and in the plant. An experiment, started in 1927, showed that the application of ammonium sulphate was very effective in restoring the health of severely diseased bushes, and this was followed up by a series of field tests with fertilisers containing sulphur and not containing sulphur, which showed that both prevention and cure are effected by the sulphate part of the fertilisers. Treatment with ground sulphur was also found beneficial. These results were corroborated by growing tea seedlings with their roots immersed in distilled water containing all the essential plant foods, and in solutions from which one of these plant foods was absent. The seedlings grown in the solution without sulphur developed the exact symptoms of 'yellows' disease even down to the scorching of the young leaves. Chemical analysis of leaves from diseased bushes showed a deficiency in sulphur, and mycological investigation indicated that the fungus *Rhizoctonia bataticola*, which is found on the roots of diseased plants, is not the causative agent, but invades the plant after its health has been sapped by the disease. The control measure now recommended is to apply ammonium sulphate or potassium sulphate in a minimum dressing of 1 oz. per old plant or ½ oz. per new plant, or sulphur at the rate of ¼ oz. or ⅛ oz., respectively. The use of kraal manure, which is rich in combined sulphur, is also advocated.

Swedish Topography.—A detailed study of the recent geology of the Stockholm region in its relation to the existing topography is contained in a paper by Prof. G. de Geer entitled "Stockholmstraktens Kvartärgeologi" (*Sveriges Geologiska Undersökning*, Sev. Ba. 12). It is accompanied by a large-scale coloured geological map of the area showing the surface geology, and much of the paper consists of a discussion of the relations to one another and the sequence of the moraine strata. The morphology of the region is shown to be partly determined by shatter belts and this feature is particularly noticeable in the area lying to the south of the inlet joining Lake Mälar to the Baltic. This inlet, some forty metres deep, is bordered on its southern side by a horst rising comparatively steeply to sixty or even seventy metres. This horst, like the rest of the area, was once covered by Cambro-Silurian deposits. It was then faulted downwards and so its covering rocks were better preserved than in surrounding regions. Subsequent elevation then occurred and gave the present position. The paper is provided with summaries in English of several of its sections.

Scattering of X-Rays by Amorphous Media.—The *Physikalische Zeitschrift* for Aug. 15 contains two papers dealing with the scattering of X-rays by 'amorphous' media. In the first, by Menckc, the scattering is studied in the 'atomic' liquids mercury and gallium, and in carbon tetrachloride. A filtered beam of X-rays falls at a small angle on the liquid surface, and the scattered intensity shows periodic variations with angle. From these one may deduce the structure of the liquid as expressed by a curve showing the relative probability of various interatomic separations. The distribution is similar to that obtained by shaking up two marked balls in a lot of similar balls. The case of carbon tetrachloride is more complicated, and it appears that the scattering cannot be explained by assuming molecules oriented at random. In the other paper, by Ehrhardt, the shapes of the molecules (1,1) and (1,2) $C_2H_4Cl_2$ and (1,2) $C_2H_2Cl_2$ are studied by X-ray interference patterns obtained from the vapours. The results show the distortion of the 'tetrahedral' linkages when chlorine molecules are linked to carbon atoms, the atomic separations in the *cis* and *trans* forms of (1,2) $C_2H_2Cl_2$ and the structure of (1,2) $C_2H_4Cl_2$ as a rotational oscillation around a stable *trans* form. The paper is an interesting example of the application of X-rays to the structure of simple organic molecules.

Scattering of Light by Argon and Methane.—Rayleigh and others have found that the light scattered transversely when a beam of unpolarised light passes through argon is incompletely polarised.

The incompleteness is usually explained by assuming that the molecules behave as anisotropic electric dipole radiators, but it is also possible to explain it on the assumption of electric quadripole radiators or of magnetic dipoles. S. Parthasarathy has described (*Indian J. Phys.*, July) an experiment designed to test this point. The anisotropic dipole view alone requires that the light scattered in the plane of the electric vector from a beam of plane polarised light be unpolarised. The gases were illuminated with a plane polarised beam and the track was photographed through a double image prism by a lens of aperture F:1. A 48-hour exposure was required. The images showed that the light was unpolarised as required by the anisotropic dipole theory. A similar result was found for methane.

Free Organic Radicals.—Rice, Johnston and Evering (*J. Amer. Chem. Soc.*, Sept.) have presented experimental evidence for the decomposition of organic compounds into free radicals by heat. Paneth had previously shown that the vapour of lead tetraethyl, $Pb(C_2H_5)_4$, when mixed with an indifferent gas and passed through a heated tube, decomposed with the formation of free ethyl radicals, since the decomposed gas would remove lead mirrors from a colder part of the tube to form tetraethyl lead once more. The present authors show that a condensable gas such as steam or carbon dioxide may be substituted for the permanent gas, and that a great variety of organic compounds when heated in the range 800°–1000° decompose into free radicals, so that by removing the products rapidly from the furnace, the free radicals formed can be combined with many different metals. Acetone gives only methyl groups; propane gives 80 per cent methyl and 20 per cent ethyl; and butane gives 70 per cent methyl and 30 per cent ethyl. The half-life of the radicals so obtained is 1×10^{-3}–2×10^{-3} sec., as compared with 6×10^{-3} sec. obtained by Paneth and his co-workers. The rate of disappearance does not follow either a first order or a second order equation very well. The temperature coefficient of the decomposition into free radicals, in the case of acetone, was approximately the same as the temperature coefficient of the ordinary thermal decomposition.

Astronomical Topics

Astronomical Notes for November.—Venus and Jupiter are conspicuous morning stars. Venus is now more than a unit from the earth, but three quarters of the disc is illuminated. Mars is also a morning star, near Regulus on November 10; but it is still too distant for useful observation. Uranus is well placed for observation in Pisces, and is observable nearly all night.

Several occultations of stars by the moon are observable in London. A sixth magnitude star disappears at 9^h39^m P.M. on November 8. The Pleiades are occulted at the end of November 13 and beginning of November 14, but the moon is only 18 hours past full. Disappearances occur at 10^h30^m, 10^h53^m and 11^h4^m P.M. Re-appearances (at the dark limb) at 11^h22^m (angle 197°), 0^h6^m (angle 274°), and 0^h26^m (angle 241°). Regulus is occulted on the morning of November 21; disappearance 7^h51^m A.M.; re-appearance 8^h51^m (angle 274°). The angles are measured from north point through east.

A good display of the Leonid meteors is likely to occur this year, but it is impossible to predict what longitudes on earth will be most favoured; the most likely time of maximum is in daylight on November 16, but watch should be kept for two or three nights preceding and following this. The Astronomer Royal has requested the Directors of Kodaikanal and Helwan Observatories to telegraph to the B.B.C. if they see a rich shower. The B.B.C. will broadcast the telegrams if they arrive before the stations close down. The radiant (near Gamma Leonis) does not rise until nearly 11 P.M., so watch need not begin until then. Tempel's comet, associated with these meteors, may also be detected in November; search ephemerides are given in the B.A.A. Handbook for 1932 and (with shorter time intervals) in B.A.A. *Journal*, vol. 42, No. 10. The earth on November 16 is only half a million miles from the comet's orbit.

The minor planet Vesta is in opposition on November 22, and is visible in a binocular, being brighter than mag. 7. An accurate ephemeris is given in the B.A.A. Handbook for November; the following will probably suffice to find it:—

	R.A.	N. Decl.
Nov. $5^d\ 0^h$	$4^h\ 14{\cdot}8^m$	12° 42′
13	4 7·2	12 27
21	3 58·8	12 15
29	3 502·	12 8

Vesta is 5′ south of λ Tauri on the evening of November 22. Conveniently observable minima of Algol occur on November 3, 9^h P.M., November 6, 6^h P.M., November 23, 11^h P.M., November 26, 8^h P.M.
